A female patient, æt. 26, single, laundress, and a native of Ireland, was admitted to the New York Hospital Feb. 10, 1879. She had never had rheumatism. Three years ago she had chills and fever. Three weeks ago, while ironing, she suddenly "began to feel badly," and went to bed. She had chills—four or five every day—fever, and severe sweats. Her right arm, fingers, shoulder, and right side of neck and back were swollen, hot, and painful. All those symptoms lasted until one week ago. Up to that time her menses were regular, but then ceased unexpectedly. Five days ago swelling, pain, and heat appeared in her ankles and legs up to her knees. The integument was bright-red, hot, swollen, and painful. The pain and heat extended up the left thigh to the groin. On admission, her eyes were bright; tongue dry and hard; pulse, 160; temperature, 106° F.; and respiration, 55; face anxious; and bowels constipated. Skin showed patches of discoloration over ankles, legs, and knees. Treatment: brandy, quinine, and salicylic acid.

Feb. 11th.—Patient delirious, and had five loose stools. Temperature, 103° F. in morning, 106° F. at noon, 104° F. at 2 P.M., and at 4 P.M. began to rise again. Pulse feeble. Patient died at 8.20 P.M., with temperature of 107 $\frac{8}{10}$ ° F.

Autopsy.—Body not emaciated. Patches of discolored skin over both legs, and of a bluish color. Œdema of both lower extremities marked. Subcutaneous fat over abdomen about two inches thick. Small amount of reddish fluid in peritoneal cavity; no peritonitis. The diaphragm on the right side rose to the second, and on the left side to the third intercostal space.

Heart.—Muscular tissue pale, yellowish brown, and yellow streaks; post-mortem staining of valves and aorta; valves competent and aorta atheromatous.

Lungs congested and somewhat œdematous. Bronchi contained frothy mucus; mucous membrane reddened and thickened. Bronchial glands enlarged. Old fibrous thickening in upper lobe of right lung.

Spleen enlarged and softened; weight, 430 grammes; pulp of syrupy consistence.

Kidneys.—Capsule adherent in places, soft, pale, anæmic; increase of fat in cortex; several whitish streaks in pyramids.

Liver pale, anæmic, fatty.

Intestines normal.

Ovaries.—Both contained small cysts.

Uterus.—Mucous membrane softened and pale.

Veins of pelvis normal.

Brain and its membranes normal.

Joints.—Collections of pus found in right wrist-, elbow-, ankle-, and in left elbow-, ankle-, and shoulder-joints. The femoral vein on the left side contained a thrombus, extending from Poupart's ligament more than half-way to the knee, broken down

into a reddish pus in places, and adherent to the walls of the vessel, which were discolored. On the right side the vein showed a normal clot and post-mortem staining.

Microscopical Examination.—Heart: muscular tissue very fatty. Kidneys: large colonies of micrococci were found plugging up the capillaries of the Malpighian tufts in places. In the *liver* many patches of pigment were found, but no micrococci.

DR. PEABODY thought the case seemed to confirm Virchow's theory that pyæmia was not a single, but a duplex disease, having phenomena dependent upon embolism, and other phenomena dependent upon absorption of some more subtle poison into the blood.

DR. L. A. STIMSON referred to a recent paper by Kocher, in which was given an account of experiments that might aid in explaining the appearance of bacteria in abscesses without an external wound. The conclusions reached by Kocher were that, in connection with wounds made in the shaft of long bones and treated antiseptically, the animals did perfectly well until fed upon putrid food for one or two days, and then the pus became offensive, and bacteria were found in the medullary canal. The same author also mentioned two or three cases of pyæmia developed in connection with strumous enlargement of lymphatic glands, and one case in which pyæmia occurred after catarrhal inflammation of the intestine.

DR. PEABODY remarked that Billoreh had reached the conclusion that bacteria were simply carriers of infection; that they were found in wounds which did not do badly and no pyæmia followed, and yet after other wounds presenting the same appearance pyæmia was developed.

ANEURISM OF THE RENAL ARTERY.

DR. L. A. STIMSON presented an aneurism of the renal artery. It was removed from the body of a man, sixty-five years of age, who died of gouty kidneys. When first removed it was about one-half an inch long, and of ovoid shape. It was situated just above the bifurcation. There were also several fusiform dilatations of the branches of the artery. He had not found a recorded case of aneurism of the renal artery. There were no other aneurisms in body.

EXOSTOSIS FROM RIGHT PARIETAL BONE.

DR. Stimson also presented an exostosis of the right parietal bone, remarkable for its density and its size. It was removed from the skull of a woman who died in the almshouse, and measured eight centimetres in length by four and a half centimetres in thickness. There was no diploë in any portion of the specimen, and there was no indication whether the growth began in the periosteum or in thickness of the bone. It was nearly as solid as ivory.

GENERAL ENCEPHALOID SARCOMA.

DR. Stimson also presented a number of specimens taken from the body of a man forty-three years of age, who died of extensive malignant disease. In March, 1878, a small tumor was removed from his right breast by operation, and was said to be cancer. Shortly after he entered the hospital complaining of indefinite pain, which was followed within a few weeks by complete paralysis of both lower extremities and incomplete paralysis of the upper extremities. He subsequently regained control of the upper extremities. About one month before death spontaneous fracture of the left femur occurred at the junction of the middle with the lower third. He had inconti-

nence of urine, and constipation, and also several convulsions.

At autopsy, the scar left after the operation upon the right breast was found soft and smooth. There was one enlarged gland in the corresponding axilla. The lungs were studded with nodules, varying in size from a pea to a hickory nut, of firm consistence, gray in color, and there were a few vascular streaks running through them. They furnished, upon scraping and pressure, abundant milky juice. The heart, liver, and spleen were normal. One kidney contained two, and the other three small nodules. The brain contained about ten nodules, varying in size, and some of them had undergone cystic degeneration. One nodule near the surface of the brain was about three-quarters of an inch in diameter, not adherent to the dura mater but firmly attached to the arachnoid and pia. The skull showed degeneration of the same character in three places; that is, the inner table had been absorbed and the diploë was occupied by a soft brownish mass which furnished the same milky juice by scraping. There was one large lump in the lumbar region upon the right side of the spine, and several nodules scattered along the spine. The spinal cord was not involved nor was there any thickening along the spinal canal. The upper four ribs upon the right side had given place to a mass of the same material; the bones having entirely disappeared. The three lower lumbar vertebrae had undergone the same degeneration. The intervertebral discs remained in large part unchanged. The same change had involved almost all of the right ilium. The head of the right femur had undergone the same degeneration. There was no inflammation of the joint, and the cartilage remained unaffected. The left femur at the seat of fracture showed that the bone had been absorbed by the same gray pinkish material originating in the medulla and spreading downwards, but not to any great extent upwards.

INTRACAPSULAR FRACTURE OF THE NECK OF THE FEMUR.

Dr. Stimson also presented a specimen of intracapsular fracture of the neck of the femur occurring in a man 61 years of age. He fell on the 7th of December, 1878, and immediately complained of inability to walk and of pain in the left hip. He was removed to the Hospital, and when Dr. Stimson saw him, two days afterwards, there was neither shortening, nor deformity, nor ecchymosis. Four days after the accident there was a slight amount of eversion and one-fourth of an inch shortening. When he next saw him, about seven weeks afterwards, there was shortening to the extent of two inches; at least the trochanter had ridden two inches above the ischio-iliac line. One peculiarity of the deformity was forcible adduction of the limb. At autopsy it was found that the fracture passed directly through the neck three-quarters of an inch from the bottom of the digital fossa.

He was told by the gentlemen who made the autopsy that the capsule was not open, that there was no ecchymosis outside, and a slight effusion inside of the joint.

Dr. Post remarked, the case of intra-capsular fracture was interesting in connection with the statement made by Sir Astley Cooper, that shortening was greater in intra-capsular than in extra-capsular fracture of the neck of the femur, and subsequently shown to be erroneous by Dr. Robert W. Smith, of Dublin. If a case was examined immediately after the fracture occurred the shortening was almost invariably greater in the extra-capsular than in the intra-

capsular, except when there was impaction. In cases in which there was no impaction the minimum shortening in extra-capsular fracture was one inch, whereas the maximum shortening in cases of intra-capsular fracture was about one inch. In the specimen presented by Dr. Stimson there seemed to have been no shortening at the beginning, but a shortening of two inches at a later period.

Dr. Stimson remarked that two years ago he presented a specimen of intra-capsular fracture in which there was shortening of two and one-half inches two days after the accident occurred.

About two months ago he presented an almost pure extra-capsular fracture in which there was no shortening, and no deformity for nearly a month after the accident.

Dr. Howe thought the specimen referred to last by Dr. Stimson was not a fair case of extra-capsular fracture, because there was sufficient unbroken bone beyond the capsule to prevent any shortening for at least one or two days.

With reference to the specimen just presented by Dr. Stimson, he did not think it possible that two inches shortening could occur even in seven weeks, without rupture of the capsule in a case of intra-capsular fracture.

Dr. Stimson thought the anatomical relation of the parts would permit that amount of shortening without rupture of the capsule.

SARCOMA OF THE CONJUNCTIVA—AMYLOID INFILTRATION AND DEGENERATION.

Dr. C. S. Bull presented a specimen of sarcoma of the conjunctiva which had undergone amyloid infiltration and degeneration.

The patient was a young girl, at. 17, of robust health. The tumor began in September, 1878, by a small swelling at the outer angle of the right lower eyelid. This slowly increased in size, without any pain or signs of inflammatory action, until by its size it began to press upon the eye and occasion some inconvenience. There was considerable deformity by the bulging outwards of the lid, but the skin was freely movable over the growth, and the orbicular muscle unimpeded in its action. On everting the lid, which was done with some difficulty, there was seen a pale, irregularly quadrilateral growth, its long diameter corresponding with that of the lid, about seven-eighths inch long, one-half inch wide, and one-quarter inch thick, with an upper surface irregularly concave. The tumor was hard and resisting, apparently bloodless, could be moved, and seemed to be firmly attached at only one point to the external angle of the orbit. An incision was made along the ciliary margin of the lid, and the growth easily dissected out. The conjunctiva of the cul-de-sac was then dissected up in all directions, and its edge brought forward and attached by sutures to the skin at the edge of the lid. The wound healed readily.

The growth on examination proved to be a sarcoma of the conjunctiva and tarsus, which had in part undergone amyloid degeneration. The epithelium in places was enormously thickened, and the sarcoma cells were of the small round character, with occasional fusiform cells and larger round cells with several nuclei. The mass of infiltration was towards the centre of the growth. The walls of the blood-vessels were also involved.

ONYCHIA MALIGNA.—The free application of bis-muth subnitrate is highly recommended for the cure of *onychitis maligna*.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Feb. 20, 1879,

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

PANAX QUINQUEFOLIUM, THE CHINESE PANACEA.

DR. H. G. PIFFARD gave a brief account of the above remedy, and of the high estimation in which it was held by the Chinese.

It is the *ginseng* root, and is regarded by the Chinese as a cure for all human ills.

SUPPLEMENTARY RECTAL ALIMENTATION, AND ESPECIALLY BY DEFIBRINATED BLOOD, AS APPLICABLE TO A LARGE NUMBER OF CASES FOR WHICH NUTRITIVE ENEMATA HAVE NOT HERETOFORE BEEN EMPLOYED.

DR. ANDREW H. SMITH read a paper upon the above subject, and gave the results obtained in eighty cases of different diseases in which rectal alimentation by means of defibrinated blood had been resorted to as an aid to stomach alimentation. At the present time there was scarcely any affection in which it was regarded as well to withhold what nourishment the stomach craved. Not only that, but disease was to be regarded as a burden which could be better thrown off by increasing than lowering the vital power, hence supporting instead of reducing treatment had been adopted, and the old antiphlogistic regimen had become a thing of the past. If it was accepted that the chances of recovery in the vast majority of cases were promoted by keeping nutrition as near as possible up to the normal standard, the question arose how could the object be best obtained? The most natural means were the best, so long as they were adapted to the indications. But if the stomach could not receive food and proper assimilation follow, it became necessary to resort to other methods of sustaining nutrition. A general reference was then made to the conditions which rendered it impossible to sustain nutrition by means of food introduced into the stomach, and special mention was made of the exhaustive paper upon the subject of Rectal Alimentation, read before the Academy by Prof. Austin Flint.

ATONIC DYSPEPSIA—WEAK STOMACH.

DR. SMITH referred first to the treatment of cases which in popular language were known as cases of weak stomach, or atonic dyspepsia. There was a circle in that class of cases which might read atonic dyspepsia produced poverty of the blood, and poverty of the blood produced atonic dyspepsia. In many cases the blood was affected first, and the stomach secondarily, such as cases of severe hemorrhage, renal disease, etc.; and in many others the primary attack was upon the stomach, such as came from diseases affecting the organ itself, or organs intimately associated with the stomach, such as the liver, etc. In both classes of cases the need in nutrition could be supplied by *supplementary* rectal alimentation; use the rectal injections to supplement alimentation by the stomach. But just there the question might arise, if the stomach was to a great degree incapacitated for absorption by the *general condition* of the system, would not that incapacity also extend to the rectum? Dr. Smith answered the question in the negative. The stomach was the centre of reflex action; with the rectum it was different, and it suffered but little from reflex disturbance. For other reasons also he believed that the rectum would continue to absorb aliment long after the stomach had refused to per-

form its functions. Again, it might be asked did rectal alimentation do anything more than add so much nutritive material to the blood: did it help to restore to natural nutrition? If the innutrition depended upon causes which could not be removed, the aid to the stomach must be continued, but if the stomach was simply weak, rectal alimentation was curative. Dr. Smith then referred to experiments which he had made to prove that blood was readily absorbed from the rectum. An enema of three or four ounces of blood was completely absorbed within eight or ten hours, and no trace could be found in the following faecal evacuation. When eight or ten ounces were injected, a portion remained, and appeared in the faeces as a black mass. He believed that defibrinated blood was a fluid that was more nearly ready for absorption than any which had yet been used in rectal alimentation. The nearer the substance used approached the character of the blood, the less chance there was of imperfect conversion into blood. The quantities which he had used were from one to three ounces every two or three hours in acute cases, and in chronic cases from three to six ounces once or twice a day.

Reference was also made to experiments which proved that a warm was more rapidly absorbed than a cold fluid; therefore, it was probably best to warm the blood before injecting it. A small quantity of opium might be added, to overcome the colic, which was sometimes developed.

Asthenia was the prominent symptom in all the cases in which he had resorted to rectal alimentation by means of defibrinated blood. A large number were cases of *pulmonary phthisis*. There was marked benefit in about one-half of the cases in which it was tried, and the basis of the conclusion was the fact that there was immediate diminution of night-sweats, an improvement in the appetite, a lessening of the cough, a better color to the face, and reviving strength. If prompt improvement followed the use of the blood while the patient was taking tonics, cod-liver oil, etc., it was fair to assume that such improvement was due to the rectal alimentation. In all the cases of *simple anæmia*, with a single exception, he had obtained excellent results. In *anæmia from malaria* he had seen the *bruit* and the venous hum disappear entirely within two weeks after the beginning of injections of blood. In cases of *dyspepsia*, whether atonic or dependent upon gastritis, he had obtained good results. He had also employed it in cases of *anæmia from hemorrhage*, in *dyspeptic asthenia*, in *neuralgia*, and in *nervous exhaustion*. Dr. Smith reached the conclusions:

- 1st. That defibrinated blood was admirably adapted to sustaining nutrition by rectal alimentation.
- 2d. That from one to six ounces could be retained, and frequently a larger quantity could be used without very much trace of blood in the faecal evacuations.
- 3d. That in about one-third of the cases it produces more or less constipation.
- 4th. That in a small proportion of cases constipation persisted and necessitated the discontinuance of the blood.
- 5th. That in a small percentage of cases irritability of the bowels attended its protracted use.
- 6th. That it was only an aid to stomach alimentation.
- 7th. That its use was indicated in cases in which asthenia was developed by disease not involving the large intestines.
- 8th. That in unfavorable cases it was capable of giving a favorable impulse to nutrition not obtained from other sources.

9th. That its use was entirely unattended by danger.

The paper being before the Academy for discussion.

Dr. AUSTIN FLINT remarked that it was of interest and importance as one furnishing facts in two directions: 1st. The class of cases to which rectal alimentation was appropriate, together with the amount of reliance to be placed upon that form of alimentation in different affections; and 2d, the kind of diet which was best suited for nourishment by the rectum.

The author of the paper had brought facts which went to show the value of the new form of rectal diet. Dr. Flint thought it very probable that different forms of diet would suit different cases; the same as in stomach alimentation, and moreover it might be well in the same case to vary the form of diet at different periods. He had not had any personal observation in the use of defibrinated blood as rectal food. During the last two years, in Bellevue Hospital especially, he had seen rectal alimentation employed pretty largely, and could make the general statement that it had proved very satisfactory. The form of diet which had there generally been employed was milk and eggs, with the addition of a small quantity of spirits and opium.

Liebig had started with the assumption that the large intestine had no power of digestion; that the digestion which took place there was always artificial; and therefore recommended a preparation which was food brought, to a certain extent, through the digestive process before introduction into the rectum. Dr. Flint thought that view incorrect, and believed the fact was, that digestion took place in the large intestine. Reference was made to a case in Bellevue Hospital, in which symptoms were present that rendered it probable that there was carcinoma of the stomach. During the periods in which it had been impossible for the patient to take food by the stomach, nutrition had been sustained by rectal alimentation, and it was an interesting fact that after rectal alimentation had been continued for two or three days the patient was able to again retain food upon the stomach.

Dr. A. E. M. PURDY referred to four cases of *nervous anemia* in which he had used the defibrinated blood with more benefit than any other form of rectal food that was employed. Milk, Leube's extract, etc., were employed, but the most rapid and manifest improvement came from the use of the blood. He thought the best results were obtained by using warm blood.

Dr. F. A. CASTLE referred to a case of atonic dyspepsia, secondary to cerebral congestion, which had been under his observation nearly two months. For about one-half of that time the patient, a female, æt. 33 years, had been sustained by rectal alimentation, and defibrinated blood had for the most part been employed. He had modified it somewhat by the addition of about one gramme of hydrate of chloral to a quart of blood. No apparent change had taken place in the appearance, consistency, and odor of the blood by that addition, nor had decomposition taken place. The tongue cleared up quickly under the influence of the rectal alimentation, and there was a marked improvement in the patient's general condition, which he attributed partly to the nutritious enema and partly to a change of air and location. At first the injections were thrown up as high as possible, but subsequently they were thrown in with a syringe having a short nozzle, and the effect was equally favorable. He warmed the blood to 105° F. Dr. Castle expressed the opinion that the plasma of the blood was the portion which was most service-

able, presuming, from the tarry appearance of the passages, that the corpuscles had remained unabsorbed. The plasma contained albuminose which was readily taken up by an animal membrane, and, if that was the important element in the blood, it was reasonable to exercise care with regard to the condition of the animal when slaughtered. If the animal had not had a full supply of food before it was slaughtered, the quantity of albuminose in the blood-plasma would be considerably diminished; whereas, if the animal had taken a full meal several hours before being slaughtered, the blood-plasma would be rich in albuminose, the probable important element.

Dr. H. G. PIFFARD remarked that the blood of cattle did not contain the amount of albuminose with which it had been accredited. Their food was mainly vegetable, and vegetable food being composed mainly of cellulose and starch, neither of which were nitrogenous, nor could be changed into albuminose, the consequence was the serum could not contain very much albuminose. Again, the serum of the blood was simply a menstruum, first for conveying nutritious products to the tissues, and second, for carrying away the poisonous products of disassimilation. The serum containing all the products of decomposition of the tissues, products which, if retained, were certainly harmful to the animal, probably was harmful when introduced into another animal. It seemed to him hardly possible that urea, uric acid, creatine, creatinine, etc., the products of disassimilation, of death, could be regarded as useful alimentary agents. Almost the only constituents of the blood which could be regarded as possessing any special nutritive value were the blood-corpuscles. The corpuscles did not contain the products of decomposition, and if they were separated, would probably be of greater value as a nutritive agent than the corpuscles plus the serum. The separation of the corpuscles from the serum was not difficult, and Dr. Piffard thought comparative experiments should be made for the purpose of determining which of the two, the serum or the corpuscles, was the better nutritive agent.

Dr. SMITH, in closing the discussion, remarked, he had no doubt Dr. Flint was correct in his opinion that a certain amount of digestion took place in the rectum. He had examined the dejecta in a few cases microscopically, and had failed to find any considerable number of blood-corpuscles that had not been broken down into a homogeneous mass of granular material. Thinking that it was nothing more than the temperature of the body that had produced the change, he subjected defibrinated blood to the temperature of the body, and found at the end of ten or twelve hours that the blood corpuscles remained unchanged. Hence the conclusion that the change produced in the rectum was something more than that due to temperature, and probably it was due to a digestive process.

With reference to Dr. Piffard's objection, Dr. Smith thought there was considerable vegetable albumen in food taken by cattle, especially if roots were fed, and that the vegetable albumen could be converted into a kind of albuminose. So far as excrementitious material in the serum of the blood was concerned, Dr. Smith thought there was not a great quantity present at any one time in a healthy animal, inasmuch as it was constantly being thrown off by the intestines, the kidneys, and the skin, and if the quantity present would harm the animal to which it was given it would harm the animal from which it was taken.

With the view to determine what the effect of rectal alimentation would be upon a healthy person,

whether or not it would diminish the desire for food, Dr. Smith had experimented upon himself, using four ounces of diffrinated blood as an enema at night. The first morning after using an injection, there was diminution in appetite, and for two days the injections gave him some inconvenience, but after that time he was not conscious that anything unusual had occurred, and, if anything, his appetite was improved. At the end of six days he found that he had gained in weight one pound, and he believed the gain was not accidental. The principal superiority which the rectum possessed over the stomach as an avenue through which nutriment could be introduced was the diminished liability to be affected by disturbing influences.

The Academy then adjourned.

OBSTETRIC SECTION.

Stated Meeting, February 27, 1879.

DR. SALVATORE CARO, CHAIRMAN.

CAULOPHYLLUM IN THE LATTER MONTHS OF PREGNANCY.

DR. SELL referred to additional cases, illustrating the beneficial effect of the concentrated extract of the root of the caulophyllum in controlling abdominal pain during the last months of pregnancy. He administered it in doses of from ten to twenty drops. He had found it useful for arresting threatening premature labor.

DOES UTERO-GESTATION EVER EXTEND TO THE END OF THE TENTH MONTH?

DR. A. C. POST referred to a case in which there was very probably a deviation from the general rule, and pregnancy continued *ten* months. The woman was the mother of several children, and had always been able to calculate with great precision the time at which she would be confined. At the end of the ninth month labor pains came on, and preparations were made for the event, but the pains ceased and she went on a full month from that time, when she was delivered of a child, which weighed two pounds more than either of her previous children, and bore the marks of greater maturity.

DR. SELL remarked that conception sometimes occurred before and sometimes after menstruation, and the length of time between those dates might be nearly one month. That fact was to be taken into consideration in connection with seemingly long pregnancies, although he did not wish to be understood as saying that utero-gestation of *ten* months' duration could not occur.

DR. POST remarked that the law allowed a pregnancy extending to ten and a half months to be legitimate.

DR. CARO remarked it was the law in Italy and France that no woman was permitted to take a second husband until nine months had elapsed after the death of her first husband.

He thought it probable that every practitioner had met with cases which indicated unusual length of intra-uterine life. Reference was made to two cases, which gave the following history:

Two young women, sisters, were married. A few days after marriage each had her menstrual period, and then the menses ceased. They dated the commencement of utero-gestation from the last menstruation. Allowance was made for the length of time between the termination of one menstrual period and

the beginning of another, and yet the length of utero-gestation was ten months. One of the women, at the end of the ninth month precisely, was taken with labor pains; the membranes ruptured and a large quantity of water escaped. The pains disappeared, and she went on for thirty-six days, when she was delivered by forceps of a female child.

In the second case, the conclusion was reached that the child was ten months old when born, making allowance for the fact that intra-uterine life was longer in breech than in vertex presentations. The child when born, weighed 13½ pounds, the sutures were solid, the fontanelles were nearly closed, and it was very vigorous.

The Section then adjourned.

Correspondence.

FULLER'S TABLETS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In a paper read by Dr. Robert M. Fuller before the New York Academy of Medicine, and published in *THE MEDICAL RECORD*, March 9, 1878, my attention was drawn to his mode of administering different medicines in tablet form. A short time later I obtained one of Dr. Fuller's plates, with the intention of trying it thoroughly. Practising medicine in a small city, where physicians carry with them in their daily rounds a pocket-case of "immediate remedies," the idea struck me as being one which would save much inconvenience, as well as secure accurate dosage. I accordingly entered into the manufacture of the tablets for my private use, and after a year's experience desire to offer some suggestions which have been learned by practice, and which may be useful to those who wish to avail themselves of this valuable contribution to our *armamentum medicum*.

Many of the instructions of Dr. Fuller have in my hands been found to be perfectly impracticable, and, if followed, might lead to an abandonment of this plan of dispensing.

His mode of saturation I have found unsatisfactory: for—1st. The medicament, in drying, appears to remain on the outside of the tablet, while within it is unaffected; 2d. Accurate saturation is impossible of accomplishment; for example, if required to medicate 50 tablets with 50 drops of a solution of atropine, $\frac{1}{16}$ of a grain to the drop, some will absorb more and some less of the solution.

A plate containing 50 holes 5 mm. in diameter and 3 mm. deep requires 60 grs. of cane-sugar and 55 grs. sugar of milk to make 50 tablets. This size of tablets is the most convenient. In the preparation of those to contain tinctures, as aconite, nux vomica, etc., I add to the sugar (and after thorough trial prefer cane-sugar to sugar of milk) the required quantity of the desired tincture. If, for example, each tablet is to contain 1 drop of Squibb's tincture of aconite, 50 drops are added to 60 grs. of sugar, and mixed intimately; adding alcohol of 95 per cent. if the mass is not sufficiently moist; allowing the excess to evaporate while stirring, if too wet. One hundred drops of the ordinary tinctures of the U. S. P. will moisten sufficiently 120 grs. of cane-sugar. Of course, any number of drops may be added, and any degree of strength given them, by using the desired amount of tincture, and allowing to evaporate to a proper consistency.

In the preparation of tablets to be medicated with the fluid extracts, a different course must be pursued. The necessary amount of the fluid extract should be thoroughly incorporated with the sugar, and there allowed to dry by spontaneous evaporation. Then reduce to a paste by the addition of alcohol, and proceed as before.

In all cases a bone or horn spatula should be used in spreading the mass upon the plate. Many of the salts that can be used in tablet form, as Hydrg. bichlor., are so easily reduced, that an iron or steel spatula destroys them, besides making the tablets black and unsightly. Again, if a rubber plate is used, and glass is preferable, the crystals of sugar will cut into the plate, and, helped by the spatula, grind off little particles of the rubber, which give to the tablets a dusky appearance.

In the preparation of tablets composed of salts only, as muriate of ammonia, or chlorate of potash, the paste is much better made with water, and the addition of about 5 per cent. of pulv. acacia insures a finer pill, less liable to break down, and does not interfere with its solubility.

Masses which contain ingredients soluble in alcohol, as salicylate of soda, should be allowed to dry to the utmost extent consistent with a sufficient degree of softness for spreading. Otherwise the tablets will stick in the holes and to the punches, and it will be found impossible to remove them from the matrix.

Punching the tablets from the plate by a rounded stick, or by shaking, is theoretically good, but experience proves it laborious and unsatisfactory. Messrs. Shepard & Dudley have constructed a little machine which answers the purpose far better, and at the same time preserves to the tablet its form and beauty.

Of course, in all these manipulations, as well as in others of a like kind, a certain amount of dexterity is needed, which practice alone will secure; but when once gained, the practitioner will find the home manufacture exceedingly easy, and the use of these little tablets not only elegant and accurate, but attractive to his patients, especially children.

Alcohol of 95 per cent. is about the lowest percentage that can be used in making the mass. Water, except in the case of tablets composed of salts alone, cannot be employed, as it dissolves the sugar and makes the tablets sticky, and so diminishes the bulk that the mass cannot be accurately divided on the plate.

In dispensing, a little cotton should be placed over the pills before putting on the cover of the box.

In making the tablets attention must be paid to the bulk of the material used. For instance, in making tablets containing $\frac{1}{2}$ gr. of morphine sulph., 100 gr. of sugar, and $12\frac{1}{2}$ gr. morphine will make 100 pills, the bulk of morphine being greater than sugar.

I lay these suggestions before you, believing that they will interest the profession, and with the sincere hope that a more intimate acquaintance with Dr. Fuller's method may induce practitioners to make a trial of it; feeling assured that when once tried, it will not be abandoned for the more unreliable sugar and other "coated" pills.

Respectfully yours,

H. L. S.

CHLORAL AS A VESICANT.—Mixed with gum tragacanth into a mass and spread on paper, it produces a blister without pain when applied to the skin. It, by the absorption of a portion, causes the patient to fall asleep during its application. Its action is mild, though not as uniform as cantharides.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from March 15 to March 22, 1879.

ROSSON, R. L., 1st Lieut. and Asst. Surgeon. Dismissed from the service of the U. S., to take effect March 22, 1879. G. O. M. O. No. 13, A. G. O., Feb. 25, 1879.

CONTAGIOUS DISEASES.—WEEKLY STATEMENT.—Comparative statement of cases of Contagious Diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending March 22, 1879.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-sphal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Mar. 15, 1879.	0	7	215	1	17	39	0	0
Mar. 22, 1879.	0	5	179	1	5	36	0	0

TAPE-WORM IN CUCUMBERS.—At a late meeting of the Academy of Sciences of Philadelphia, Prof. Dr. Leidy exhibited a specimen of tape-worm found within a large cucumber. This specimen was a true tape-worm, but of an unknown species, the ovaries being confined to the anterior extremity.

CARBONIC ACID GAS.—Wet pepper, it would seem, is a powerful generator of carbonic acid gas. An English vessel had a large quantity aboard, a part having become wet by rain. The next day a Chinaman went into the hold and fell senseless. Four sailors, on going to his rescue, likewise became insensible. After ventilation of the hold, all five persons were found dead.

FROZEN SECTIONS OF A CAT.—At the meeting of the Cornell Philosophical Society, at Ithaca, N. Y., Feb. 8th, Prof. B. G. Wilder showed some frozen sections of a cat recently prepared with the aid of Mr. S. H. Gage. The cat was killed with chloroform, and injected with red and blue plaster so prepared as to remain hard in alcohol. (See Mr. Gage's paper on the use of plaster for injections in the *American Naturalist* for Nov., 1878.) The cat was then supported in a natural position, with hay, and frozen solid. The sections were made with a fine saw and at intervals of one cm. Each section was immediately cleaned and placed in strong alcohol. The position of the viscera and injected vessels is perfectly shown, and the preparations are permanent.

THE SUCCESSOR TO THE LATE JOHN B. BIDDLE, M.D., IN THE CHAIR OF MATERIA MEDICA AND THERAPEUTICS IN JEFFERSON MEDICAL COLLEGE.—The Trustees of Jefferson Medical College, at a meeting held in their rooms in the College Hospital in Philadelphia, on Tuesday evening March 18th, elected Robert Bartholow, M.D., Professor of the Theory and Practice of Medicine and of General Therapeutics in the Cincinnati Medical College, successor to the late John B. Biddle, M.D. The other candidates for the position were Drs. J. Solis Cohen, John L. Ludlow, James C. Wilson, Henry Hartshorne, John C. Reese, and

Lawrence Turnbull, of Philadelphia; Robert Bolling, of Chestnut Hill; James Darrach, of Germantown, and W. C. Reiter, of Pittsburgh, Pa. The election was very closely contested, Dr. Bartholow not receiving the necessary number of votes until the fifth ballot. The Trustees, at the same meeting, declared the Chair of Demonstrator of Anatomy in the college vacant, resolving that in future the demonstratorship of anatomy should be filled by the vote of the Trustees and not by that of the Faculty. The former incumbent was Dr. Thomas H. Andrews. The applicants for the new appointment are Drs. Henry C. Chapman, J. Ewing Mears, and W. W. Keen.

A STRANGE FACT.—Some fifteen years ago a workman of Marseilles lost his only child. In despair at his loss, he cut off one hand of the child and preserved it as a precious souvenir in a jar of alcohol. One month ago the man's wife was confined a second time, and gave birth to a healthy boy. Strange to say, the child had but one hand; the hand that was wanting corresponded to the amputated hand in the jar.

HYPODERMIC INJECTIONS OF MORPHINE FOR AFTER-PAINS.—Dr. Ernoul recommends the employment of hypodermic injections of morphine, when the after-pains are exceptionally violent and obstinate. He injects $\frac{1}{8}$ of a grain of the hydrochlorate in the hypogastric or iliac region, at the point where the pain is felt with most intensity, and repeats the injection, if necessary, two or three times in the twenty-four hours. —*Gazette Obstétricale.*

PERCHLORIDE OF IRON TOPICALLY TO CHANCRES.—M. Rollet recommends:

℞. Ferri perchloridi, Acid. hydrochlor.,
Acid. citrici $\bar{a}\bar{a}$ $\bar{\zeta}$ i.
Aquæ destil. f. $\bar{\zeta}$ i.
M. Apply on limb.

PRURITUS VULVÆ.—Dr. Mendenhall recommends (*Obstetric Gazette*, Dec., 1878):

℞. Sodæ biborat. $\bar{\zeta}$ i.
Plumbi acetat. $\bar{\zeta}$ ss.
Tr. opii. f. $\bar{\zeta}$ j.
Aquæ destil. f. $\bar{\zeta}$ viij.

M. Sig.—Soak cloths in the solution and lay them upon the external parts affected, between the labia, etc. Keep the cloths freely wetted. Inject one ounce of the solution into the vagina several times a day. When the pruritus has been subdued, apply a solution of carbolic acid in glycerine (gtt. xx. to f. $\bar{\zeta}$ i.) once or twice daily.

ERGOTINE HYPODERMICS IN EPISTAXIS.—Dr. Porak (*La Tribune Médicale*) cites three cases of obstinate nasal hemorrhage, each of which was promptly arrested by a single hypodermic of ergotine. His formula was: Boujean's ergotine, 2,000 gmm.; Glycerine, 30,000 gmm. M. 20 drops hypodermically in the lip or cheek.

LEPROSY.—Chaulmoogra oil, obtained from the *gynocardia odorata*, has been used with much success in India in leprosy, tinea, herpes, scrofula, and rheumatism. It is official in the Pharmacopœia of India. There is an ointment; there are, also, *perles*, each containing four minims. Both are prepared by Messrs. Corbyn, Stacey & Co., of London, England.

TO MAKE POULTICES.—Dr. T. Lauder-Brunton says ("Brain"), the proper way to make and apply poultices is the following: Make a flannel bag the size of the required poultice. Fill the bag with the linseed

poultice made as hot as possible, and place between this and the skin a piece of flannel doubled. Over the poultice wrap more flannel or cotton-batting.

POISONING BY OIL OF CHENOPODIUM.—A very interesting and novel case of "Poisoning by Oil of Chenopodium" is reported by Prof. Dr. Thomas R. Brown in the November number of the *Maryland Medical Journal*. One ounce and a half proved fatal *five days after* ingestion, profound coma and a very high axillary temperature attending. This article will bear careful perusal, since no works on materia medica or forensic medicine detail any fatal case of poisoning from this drug.

COD-LIVER OIL EMULSION.—℞. Cod-liver oil, f. $\bar{\zeta}$ iv.; Glycerine and sherry wine, $\bar{a}\bar{a}$ f. $\bar{\zeta}$ ij.; Hog's pepsine, $\bar{\zeta}$ iss.; Dil. muriat. acid, f. $\bar{\zeta}$ j.; Sodium chloride, 3 ij. Agitate the oil with the glycerine, and add the wine and pepsine, previously mixed, shaking all well together; then add the acid and salt. This is claimed as palatable, being slightly acid.—*Med. Press and Circular.*

TREATMENT OF CHRONIC ALCOHOLISM.—Dr. d'Ancona, of Italy, gives gr. iss. of zinc phosphide (in divided doses) daily for many weeks with not only impunity, but with decided benefit to drinkers. He claims phosphorus gives the same comfort, strength, and force as is usually derived from the accustomed potations, and produces beneficial changes in the system even when the use of liquor has not been entirely discontinued.

CODE OF ETHICS.—Prof. Dr. H. M. Lyman, of Chicago, has made some very pertinent and able commentaries upon "The Code of Medical Ethics" in the November number of the *Chicago Med. Jour. and Exam.* He writes in a very happy vein, and fully exposes much of the absurdity contained in the "Code." We recommend our readers, and the guardians of the "Code" as well, to peruse and digest this paper.

EYE TROUBLES IN GENERAL PRACTICE.

By HENRY D. NOYES, M.D.,

NEW YORK.

(Read before the New York Academy of Medicine, March 6, 1879.)

GENTLEMEN—Fellows of the New York Academy of Medicine: The winsome ways of our honored and courteous President have brought it about that I am to read to you a paper upon a topic which may seem to convict me of a disposition to undue assumption. I have been seduced into consenting to offer you various suggestions derived from my field of work, which you may utilize in your own practice. I am not in the least reluctant to impart any acquisitions or methods, or deductions of my own, which others can profitably share, but I shrink from a position of didactic pretension to which I am not entitled. With this plea in extenuation, and promising that my contributions will be on matters of ordinary occurrence in general practice, may I not crave your indulgence for what is the same old story which was told in the beginning, when Paradise had not yet been invaded by the obstetrician, viz., the Professor tempted me and I consented.

Thus, Mr. President, having cast upon you the responsibility, both for my appearance and my topic, I salute you and enter upon my task. To the family physician the community give their confidence in a peculiar and sacred sense. Though specialties multiply and demonstrate the necessity for their being, by successes which are only attainable by diligent devotion to small fields, it will ever be true that the family physician will be the one to whom will be made known, or upon whom it will devolve to make known, the beginnings of disease, of whatever kind; and moreover he will, as now, have in his hands the treatment of many affections to which specialists devote themselves. I come to-night begging you to accept hints which may quicken your perception of the early stages of important defects of sight, may help you in curing diseases of the eye, and may make you more capable of judging when you are in the presence of such of its maladies whose proper management calls for highly trained skill.

Let me first call your attention to the importance of recognizing at an early period in the life of children the existence of serious errors of refraction. Some of them are always congenital, viz., hypermetropia, or far-sightedness, astigmatism and cataract. Another error, viz.: myopia, or short-sightedness, is not usually congenital, but begins at the time when children give steady attention to books. It will vary in its commencement between five and twelve years of age. At the same time very young children are sometimes the subject of extreme myopia, and then its congenital character is highly probable. This deduction is also worthy of belief when persons at twenty or twenty-five years of age are found to have myopia greater than $\frac{1}{2}$.

To put this statement into tangible form, let me offer you some statistics, kindly compiled from my private records of the last nine years, by my friend Dr. Callan. Out of 1,400 cases of erroneous refraction there have been found 102 cases in very young persons who had the high and highest degrees of refractive error, viz.: 55 of myopia, or short-sightedness,

29 of hyperopia, or unnatural long-sightedness, and 18 of astigmatism. The remarks above made are most emphatically applicable to these individuals, and in lesser degree to many others not quoted. I may mention a boy, H. B., nine years old, who had myopia $\frac{3}{4}$, with vision by glasses of only $\frac{1}{200}$. This lad, in delicate health, had never had glasses, and consequently had never seen anything a foot beyond his nose. All beyond was mist and mystery. He was excessively reserved and taciturn, with no animation in face or manner—unwilling to play and undeveloped in strength. A few months' experience with glasses made him a different boy in his whole appearance and character. My records will furnish many such illustrations, but I need not consume your time in presenting them. Without holding forth the extreme cases, the argument on behalf of the little ones is sound and cogent, even though they are not so distressingly afflicted as are the worst.

To this I must add the remark that proper care on the part of parents, school-teachers, and physicians, can do much to prevent or retard the acquirement of myopia at the age when it is most likely to appear, viz.: between five and fifteen. On this point much has been written, and I merely allude to the subject.

The points which I desire to impress are, that the want of suitable aid to sight, in cases so aggravated as the above, not only inflicts upon the children unnecessary discomfort and privation of enjoyment, but it has a bearing upon their character and development which is most unhappy.

As the young mind reaches out to the surrounding world, by aid of touch and taste and hearing and sight, it reasons upon the impressions brought to it, and accepts the messages which the senses deliver, as absolute truth. Of course the reasoning and collating power is at first most feeble, but as the mind gathers force it still trusts the couriers who describe the characteristics of the world outside of consciousness; and if the messengers bring falsified, or garbled, or distorted reports, the mind must be hopelessly deceived and perverted. A child may be thought a dullard, and to have no aptitude for observation or learning; he may be counted cold-hearted and unresponsive when his face does not light up at the smile of his mother or the caress of his sister; he may be esteemed sullen or stupid; he may be counted a bad playfellow; he may be thought eccentric or peculiar because he does not behave like other children. All this and more may be the character ascribed to him because his misfortune is to have bad sight. Beside this, it is a truth in mental philosophy that exactly such a character may be fastened upon him for life, because in his young days he was cut off from enjoyment of the visible world on terms of equality with his fellows. Do we not know that dim-sighted persons are apt to be queer? If their deficiencies had been noted and corrected at an early stage of life, who can say how much more symmetrical would have been their adult character, and how much happiness society and the family might have enjoyed from them.

I therefore beg to ask that if your attention is called to young children whose traits of character excite surprise, and who are considered to be strange or deficient, that you will make inquiry whether they possess good sight, and to this I may add with not less force that the possession of good hearing is in its way equally important. For the very young, viz., those under five years of age, tests of reading may not be applicable; but happily in our day the trained observer can quickly decide by the ophthalmoscope whether any error of sight exists, and also point out

the remedy irrespective of intelligent answers or co-operation on the part of the child.

I would not hesitate to give a young child the use of needful glasses for at least such periods of time as should serve to inform his mind of the true character of surrounding objects, provided the ocular defect were great enough to obscure or pervert his perceptions. In respect to congenital cataract the same remarks apply, and I mention this condition to bring out the fact, that there may be a most serious loss of transparency in the crystalline lens, which will not in the least be visible to ordinary inspection, and the pupil shall have the normal degree of clearness and blackness. The ophthalmoscope will unerringly discover the lesion, and the proper treatment will follow. Moreover, the operation ought to be done early—in healthy children by the end of the first year.

To the same category belongs, in a degree, the subject of strabismus, the foundation of which is erroneous sight. The order of events is first visual error, and then disturbance of muscular action. It often happens that if the visual error be corrected, the muscles will redress themselves, provided they have not undergone organic shortening. If this result be attained, the cure is much more likely to be of that perfect kind, which includes the obtaining of proper binocular vision, rather than that incomplete cure which makes the eyes look as if they worked together harmoniously, but consists really in the use of but one eye at a time. I grant that the defect of sight in one eye is often incurable, and that the best result may be impossible; but this misfortune should not be an excuse for omitting to discover the visual error and its quality. I do not mean that an operation can be often avoided, but I insist that the first step is to recognize the visual error before the muscles have undergone permanent perversion. Among the most intelligent persons who bring their children for examination at the very beginning of squint, I have, in not a few instances, been able, by the timely suggestion of glasses, to aid the child's sight so much that the disposition to squint has been kept under control, and the function of co-operation of the eyes been preserved until the age arrives when an operation may be most appropriate. Such treatment is the ideal method of dealing with squint.

Another matter may be briefly touched. As with the arrival of middle life the focussing power of the eye declines so far that for the usual reading distance a sufficient reserve of adjusting force no longer exists, it is decidedly the preferable thing to put on weak magnifying glasses to take off the strain, rather than to postpone their use as long as possible, either on the plea of avoiding permanent dependence on them, or because of the fear of seeming to be growing old. Not seldom the token of need of help is found in irritation of the lids, in styes, in a sense of worry about the eyes, as well as in difficulty in seeing by evening, or inability to make out the fine print of the newspapers. Every one knows that holding the book at arm's length and drawing near to the window are infallible tokens of the coming need, and yet some will stoutly resist, until, as a gentleman said to me, they need to hold the book with a pair of tongs.

I pass now to certain other matters which are partly hygienic and partly within the domain of pathology. A large class of chronic or recent invalids are surprised and distressed to find themselves unable to command the services of their eyes as they once could. Often they are alarmed with fear that organic mischief has befallen their sight. No persons present this symptom so frequently as do those who suffer from

uterine disease. It seems to matter little what may be the special form of lesion of the female generative system. They suffer from enfeebled endurance of accommodation, and equally feeble power in the extrinsic ocular muscles. They do not so much complain of indistinct or blurred vision, as of pain in attempting to read or to sew, etc. The pain may come after a little effort, or it may be constant. In extreme cases the patient cannot look in the face of one with whom she is conversing without exciting neuralgic pain. This condition is very widely prevalent, and it must have forced itself upon the notice of every observing physician. So, too, when persons are recovering from any severe illness, such as a fever, or from protracted exhaustion, or after prolonged lactation, or watching with invalids, or great loss of sleep; when there has been much grief and weeping, or after severe mental strain; also as a consequence of masturbation, or after severe loss of blood, or in severe or chronic dyspepsia, impaired eye power is pretty sure to appear. I only give utterance to your own experience when saying this, but permit me to go a little farther and say that while in the above situation the essential condition to recovery lies in restoration to vigor and sound health and habits, certain additional points are worthy to be remembered. One is, that to such people graduated use of their eyes, beginning with short periods and advancing by small additions, is a valuable means of helping them develop and recover their ocular energy. We know this plan of treatment under the name of Dyer's method. Similar to this is the use of prisms to help the power of the ocular muscles, as dumb-bells call forth the strength of the arms and shoulders.

Moreover some of these patients are destined to remain chronic invalids. I utter no malicious sarcasms upon my most esteemed friends the gynecologists, but all their patients do not get well. To such women who pitifully implore the oculist to give them some solace for the weary hours upon the sofa or in the house, it is of the highest importance to discover and to note deviations from normal states of vision, which to persons in health are of absolutely no moment. Slight degrees of far-sightedness, trifling degrees of astigmatism, must in these cases be accurately corrected by glasses, and often the relief is most keenly appreciated. So, too, faintly tinted glasses are of use, and perhaps the most common relief is found in combining weak magnifying-glasses with abductive prisms. Such persons complain of glaring light; they almost always have irritable and congested conjunctival membranes. Treatment of their eyelids and regulation of the light is of no small value. The great necessity of carefully regulating all their hygienic conditions and doing this with detail and precision I need not dwell on.

Above and beyond these cases in pathological significance are the cases of intense hysterical photophobia, or intolerance of light. Fortunately they are not frequent, but they make up in malignancy often what they lack in frequency. In some of them there will be real optical error, or perhaps erosion of corneal epithelium, but behind these lesions is a perverted nervous system, a weakened moral nature; sometimes we find the invalid's eager craving for sympathy and condolence, the gratification of a strange passion for being pitied and coddled and made the centre of a worshipping and ministering family circle. Such patients call for great firmness, tact, and penetration. They are like the bedridden girls whom no arguments can convince that they are able to get up if they will. I for a long time kept in my possession a

quilted mask made of pasteboard, cotton, and thick cloth, constructed to go from the top of the head to the mouth, which was worn like a visor by a patient who would not allow me to take it off or have the least glimpse of her eyes. By putting her under chloroform I convinced her she could face the light and I robbed her of her visor. For a certain period she was made much better, but again relapsed.

To return to the eyes of weakly people who are only too anxious to comply with suggestions aimed for their good. In the first place, they need much comforting and encouragement. They should always be addressed hopefully, not to deceive them by promises of perfect recovery, but that they will at least attain a degree of ocular function which they can rely upon for permanent use, and that they must have care for eye strength as for any bodily strength; that they will not lose their sight, and that if they get well in health their eyes will in the end be restored. Moreover, if they have had to use glasses they will probably put them away, as other patients get rid of canes and crutches, and plaster-of-Paris jackets, and the whole pitiful list of surgical testimonies to our physical frailties. To persons who do not enjoy good health certain precautions in the use and exposure of their eyes are important. Ladies who suffer from painful menstruation should not read when lying in bed at the time of their menstrual flow. Reading while lying down is almost always trying to weakly persons, because the usual method of directing the eyes is interfered with, and the ocular muscles do not act in the combinations and proportions to which, for reading in the erect posture, they are habitually adapted. To such persons, thick veils or dotted veils, or the so-called glistening illusion veils, or heavy erape veils, cause worry and retinal irritation. The modern styles of bonnets leave the eyes without any protection from the sun and wind, therefore umbrellas and parasols, or colored glasses, become needful to the sensitive. To such it is hurtful to read in railways or carriages; and to them an atmosphere of smoke, or the air of an ill-ventilated or crowded and brightly lighted room is offensive; oftentimes the viewing of a multitude of persons, or a walk along a crowded street, is painful, just as bright and flashing light or strong colors are disagreeable.

Let me here allude to the grave mischief engendered in closely packed dwellings, where no proper supply of pure air is furnished, such as in tenement-houses, over-crowded asylums, and poor-houses. In them the degeneration of health, besides manifold other ills, may bring on granular conjunctivitis. The follicular deposits and hypertrophy of tissue soon find occasion for sudden aggravation in a slight cold, and then the contagious secretion is carried from one to another until many fall victims to the miseries of this chronic disease. One who has seen much of eye disease feels most intensely how sad is the future of the tenement-house poor who contract granular conjunctivitis.

Having touched upon the subject of granular conjunctivitis, let me call attention to the loose way in which this condition is sometimes asserted to exist. Many times have I known a state of simple hyperemia declared to be granular lids, and the disease treated, perhaps, with sulphate of copper in crystal. Let me only say that it is essential to granular conjunctivitis that there be thickening of the membrane, either in minute globules, or over an extended area. Moreover, that the theory of treatment is to stimulate the tissues to absorption of the morbid material, and not to actually destroy and remove the morbid thickening, as is done in ulcers of the skin and in granulating

wounds. Hence, the stimulating remedy must not produce an excessive action. But the details of this subject would lead us too far for me to enter upon them.

Some words about conjunctival hyperemia of the lids will, I think, be fitting. The cases I have in view are not severe; there is often nothing wrong to be seen until the lids are turned over, and then a varying degree of congestion is all that appears. For this, an astringent is usually ordered, either an outward lotion or drops, and among the latter, perhaps the most frequently ordered is the very worst in my esteem, viz., sulphate of zinc, usually gr. ij. ad $\frac{3}{4}$ j. It is possible that this slight local trouble comes from cold, or over-work, or outward irritation; in such cases, the treatment will often be effective.

But I have to insist strenuously upon the fact that a large proportion, and I believe a considerable majority of such cases are connected with various forms of optical or muscular error, viz., all the forms of defective refraction and weakness of sight, and the cases of partial or incipient cataract. Not even are the amblyopic affections excluded. The explanation is most simple, viz., that whatever causes difficulty of sight, excites irritation of the conjunctival vessels. The symptoms are burning, dryness, heaviness, stickiness, scratching of the lids, and other similar sensations. Now the cure for these cases is to ascertain the cause; if possible, remove it, and also apply the soothing or alterative topical remedies.

Besides the above causes of conjunctival irritation, there are some which are to be looked for outside of the eye. One which I would most urgently bring forward is chronic nasal catarrh. In our climate this is one of the most common conditions, and it extends its hurtful influence upon all the special senses except touch. Hearing, smelling, taste, and sight are all more or less damaged. To the eye the mischief comes in troubles of the lachrymal passages, and of the palpebral and ocular conjunctiva. For six or eight years I have been compelled to treat nasal catarrh with energy and regularity, in order to enable me to cure chronic conjunctivitis as well as chronic and acute otitis media.

Another lesion, which has similar affiliations, is marginal blepharitis, the ophthalmia tarsi. True, this may be only a local and idiopathic affection, but my observation long ago taught me that the persons who had it were often subjects with optical errors, or with nasal catarrh. In this I quite agree with my friend Prof. Roosa, who has written upon the subject. The local treatment by the application of a sharp point of nitrate of silver to each little ulcer, followed up by cleanliness and a stimulating yellow oxide of mercury ointment, will readily cure the disease; but to keep it cured requires correction of the optical error, in case this should exist.

Let me offer a few hints on treatment of conjunctivitis. I do not pretend to set forth what ought to be done in all ordinary cases, but simply speak of certain special and rather unusual conditions. The form which occurs in new-born infants is, in the vast majority of cases, easily removed by luke-warm water, or by such simple astringents as alum or borax. But the decidedly purulent form, with puffy lids and creamy discharge, cannot be safely left to such means. I would not speak to a point which seems so self-evident, had it not been suggested to me by the remark of a medical friend that, having attended 1,500 confinements, he had never seen but three or four cases of bad sore eyes among babies, and when he asked me to assist him in caring for one such bad case, he was con-

siderably surprised at the treatment which I instituted. The lids must be thoroughly everted, and to the red and swollen membrane, as it unfolds, a solution of nitrate of silver, five grains to the ounce, must be well applied by a brush; both lids must be thus treated, and the application repeated as the discharge again becomes thick, viz., in from twelve to twenty-four hours. Meanwhile careful wiping away of the secretion, the use of an alum solution, and greasing the skin to avoid excoriation are in order. The caustic to the everted lids, in severe cases, is what I have to emphasize, and this, in *bad* cases, will be ten grains to the ounce, or be the mitigated stick, one part to two. Should the cornea be threatened by perforation, other and skilful advice ought to be summoned, as paracentesis, etc., may be needful. Again, in the violent forms of purulent conjunctivitis in adults, whether gonorrhoeal or not, besides continuous application of iced water and the use of caustic, I lay great stress on the relief of the pressure of the swollen lids by deeply and extensively incising the outer commissure—to do this when the lids are much swollen—and to repeat incisions in this way as the wound grows together, and the œdematous conjunctiva threatens the vitality of the cornea. I am most deeply persuaded of the value and imminent necessity of this proceeding in severe cases.

For the great number of cases of decided conjunctivitis nitrate of silver is the best remedy, and rarely, in my judgment, does it need to be more than gr. v. or x. ad ζ i. But cases arise in which this remedy fails to cure. We find this fact among old persons, and in hydremic subjects. I have also seen it in young infants. In fact, however, it is no easy thing to thoroughly turn the eyelids of a baby of a week old inside out; not a little skill in manipulation is often necessary to do it well and with unnecessary pain. The normal way in which the nitrate of silver acts is as follows: the caustic makes a slough of the epithelium; this is cast off with serous transudation, and the unloaded vessels then find relief, and the emigration of pus-cells is abated. Such is the process in the vigorous, and when the pus again appears in quantity, the application is renewed; but to the feeble, and especially the old, the tendencies are to less vigorous action, and the recrudescence after the slough comes away, is less perfect. In fact, the formation of pus may be made more abundant than before. For such cases the remedy is tannin in glycerine, gr. xx. to lx. ad ζ i., painted upon the everted lids. Its action is most satisfactory and direct. So, too, for œdematous inflammations, with little purulent or mucous secretion, but with the tissues loaded with serum, a solution of tannin in water will sometimes act like magic. Such, at least, was the testimony of one of our most distinguished surgeons, who enjoyed opportunity for personal experience of this bit of therapeutics.

May I say a word about treatment of inflammations of the cornea. A well-settled axiom is, that during the acute period of trouble, stimulation is out of place; but as the stage of intense hyperemia, intolerance of light and pain abates, the eyelids may, with advantage, be touched with solution of nitrate of silver gr. iij. or v. ad ζ i. It is in the subacute stage of the phlyctenular form that the yellow oxide of mercury gr. ij. vel x. ad ζ i. of vaseline or amylo-glycerine sometimes does admirably. But in acute periods, atropine and warm fomentations are the proper thing. I am not attempting a resumé of this topic, but I wish to lead up to three suggestions, viz.: that the fluid extract of conium can be used with great benefit, notwithstanding some dangerous results have been

reported from overdoses, as a means of overcoming the palpebral spasm, which is a great aggravation of the corneal irritation, and that bromides are also clearly indicated in the same condition.

Very severe cases would be likely to demand experienced advice, and I may say that paracentesis of the anterior chamber and sometimes iridectomy I have found of immense use in some bad cases.

A combination of severe keratitis with iritis is an unhappy condition, and the bad cases will seldom yield to anything short of iridectomy. As to purulent inflammation of the cornea,—this occurs from direct injury, as by a bit of stone or steel, or as a result of great debility, or from anaesthesia of the cornea. On the last head I beg to remark that an imperfect degree of sensibility in the cornea is, I have lately found, much more common than is usually supposed.

In all these conditions, if the cornea be deeply or extensively infiltrated with pus, nothing can compare in efficacy with the free division of the structure horizontally across the cornea with a fine Graefe's cataract-knife. Precede and supplement this proceeding by atropia and steady continuance of warm fomentations, and the damage suffered by the eye will be far less than would otherwise take place. I could fortify this assertion by many cases, and I emphasize it as confirmative of the practice first introduced by Prof. Saemisch, of Bonn. As to cases of pus in the anterior chamber, with infiltration of the cornea, the lesser degrees need no surgical interference; but when the plastic or purulent material rises to occupy the lower third of the cornea, I decidedly advocate its evacuation by a free paracentesis. This is a painful operation, and may be worthy of the administration of ether. In these cases the wound heals at once, and possibly the hypopyum may form again and need a second discharge. Whereas, in suppuration of the corneal substance, the wound above advocated continues open for days and allows the fluids to drain away, to the great relief of the eye. At a later time, when the eye has recovered, an iridectomy will confer valuable sight.

I must, perhaps, guard myself from misapprehension of my meaning as to the rules of treatment, by saying that general measures of a supporting and tonic kind, generous diet and stimulants, rest in bed, avoidance of light and of irritating causes, are all supposed to be made to contribute to the desired result.

Keratitis in children is always a distressing and tedious affection. Whatever its form, the severe symptoms are the extreme dread of light, and pain, while there is always more or less danger to sight. The great difficulty of treatment is how to get local medication into and upon the eyeball. If the child refuses to open the lids, and they are often by reflex irritation incapable of doing so, there is little use in trying by the fingers or by elevators to separate them. The attempt inflicts great pain, and the view of the eye is unsatisfactory. After the disease has lasted long it is very common to find an ulceration of the skin at the outer commissure, and this is torn apart whenever the lids are forced open. This is a serious aggravation of the blepharospasm which the corneal inflammation first excites. The great remedy for extricating one's self from the embarrassments of treatment, and for giving relief to the suffering child, lies in the administration of chloroform. It was long noticed by myself and others, and Mr. Hutchinson, of London, has, with his customary acuteness, written upon it, that to give chloroform not only enables the physician to see and treat the eye, but by its narcotism has a permanent good influence on the disease

by abating the nervous spasm. Therefore, when a child has acute corneal inflammation, and buries its head away from the light and obstinately shuts up its eyes, give it chloroform so as to bring on the first quieting influence; then the state of the cornea can be inspected, an atropine solution can be freely dropped in, the lids can be everted, and to their congested conjunctival surface a solution of nitrate of silver—gr. ij.—v. ad \bar{z} i.—may be applied; or, in the later stage of the malady, the yellow oxide of mercury ointment—gr. ij.—v. ad \bar{z} i. of amylo-glycerine—may be used. Besides this, seize the opportunity to apply a pointed crayon of pure solid nitrate of silver to the skin-ulcer at the outer commissure, and freely apply it also to the abrasions which will often be found about the nostrils, lips, and chin. From these latter abrasions the scabs must be forcibly wiped away; and though the raw surfaces and fissures will often bleed, the caustic should be fully applied and the parts afterwards dressed with simple or medicated cerate. I merely give these hints as to the handling of a very common and troublesome class of cases, without attempting to depict the full treatment which must be instituted under the various stages and conditions and phases of the disease. This may be learned from the usual text-books.

Likewise may I offer some hints as to the management of iritis. For my purposes I may enumerate four principal causes of iritis—injury, syphilis, rheumatism or gout, and gonorrhœa. As to traumatic iritis, I may say in general, that the management consists in rest, exclusion of intense light, lotions of cold water and atropia, with or without leeches. The rheumatic or gouty form has these features, that when fully established it yields very slowly to treatment; that it exhibits little plastic exudation, and often is of the œdematous variety; that the patients often suffer much pain, and that the local application will generally have to be lukewarm, and will in any event not be well tolerated; that atropine must be used with moderate vigor, sufficient to dilate the pupil; and that leeches often do much good in acute cases, while paracentesis is not seldom in bad cases a valuable resort. In this class of cases, constitutional treatment is of high importance, and this will usually be of the alkaline variety. As to the merits of salicylic acid I cannot speak. Iodide of potassium and colchicum sometimes do good service, but I have found the alkalies of the greatest use. Frequently has it been possible, in subjects prone to rheumatic iritis, to abort an attack by full doses of sal Rochelle, or liquor potassæ and Vichy water. With some persons attacks are very frequent, and they depend on imperfect action of the excretions. I make it a point with such patients to insist on a great deal of outdoor exercise, on careful attention to the skin as well as to the kidneys, and occasional Russian baths. Gonorrhœal iritis is only a sub-variety of the rheumatic form, and I mention it to indicate my conviction of the potency of urethral inflammation to be the cause of iritis as well as of rheumatism. I could cite cases which have proven this relationship, and that the control of the urethral trouble was necessary to the speedy cure of the eye trouble.

Finally, upon syphilitic iritis I beg to say that in the moderate cases, the local or atropine treatment is the most essential. As to the type of the inflammation, there may be every variety of pathological lesions; but when a case of iritis exhibits a rich amount of plastic exudation, it is pretty surely syphilitic. I emphasized the use of atropia. The solution should be four grains of the sulphate to the ounce; the fre-

quency must be governed by its ability to secure expansion. Once every two hours, or four times an hour three times daily, or with any frequency needful to dilate the pupil, is the rule. The necessity of using it vigorously is too often not appreciated. The obstacles to dilatation of the pupil are, the difficulty of forcing any solution to pass through the saturated cornea by endosmosis, the fulness of the anterior chamber, the reluctance of the iritic muscular fibres to contract because the vessels are congested, and the mechanical opposition of the adhesions to the lens. The iris rests in contact with the front of the crystalline lens, both when the pupil is contracted and when it is dilated; hence, whatever the degree to which the pupil may expand, adhesions can occur and offer resistance to the remedy. The efficacy of the remedy is often enhanced by local depletion, viz.: by four leeches to the temple, placed far away from the eye. The reduction of congestion of iris vessels is favorable to the endosmosis of atropine solution. Unhappily, certain disadvantages attend the vigorous use of atropia. It causes conjunctival irritation with some people, although the solution be wholly free from acid. Some persons experience the symptoms of constitutional poisoning before the requisite local influence is secured. The substitution of daturine has sometimes served to circumvent this difficulty, and we are now in possession of a new agent called Duboisia, of which only the extract has yet come into this market, and which is asserted to be free from some of the objectionable qualities of atropia. On this I cannot offer any experience.

I strongly emphasize the beneficial change which always passes over a case of iritis, when success crowns the effort to enlarge the pupil to the uttermost. Let this effect be attained, and the vast majority of cases are speedily relieved. Should this not be possible, a different future is to be expected. Extensive pupillary adhesions will surely entail protracted inflammation, and cause mischief to sight, not only by the obstruction of the pupil, but by the accompanying haziness of the vitreous and lesions in the choroid. So disastrous is this condition that iridectomy may be done, and even *must* be done, during the height of the inflammation, and with greatly beneficial effect. Adhesions of the pupil are the great cause of obstinacy in iritis, and of the repetition of attacks.

While so much has been said of the local treatment, I am bound to advert to the constitutional treatment of syphilitic iritis. Do we need it to control the inflammation? In two conditions I think we do, viz., where there is a large amount of plastic exudation coming out in yellow masses on the surface of the iris, and also in certain cases of total pupillary adhesion. Under these conditions I recognize the need of using mercurial inunction vigorously, and can testify to its ready and happy influence. But for the common run of cases the constitutional treatment is employed only because the patient has secondary syphilis, and is not an essential factor in curing iritis. Therefore we do not ptyalize every case of iritis *secundum artem*, as was formerly held to be sound practice. But we administer the constitutional treatment according to the rules which the state of the general system imposes. Let me here remark that while iritis usually comes among the events of secondary syphilis, it may also appear during the tertiary stage of the disease.

A few words now on diathesis as recognizable in inflammations of the eye. It was the nosology of former times to designate a serofulous ophthalmia,

and rheumatic ophthalmia, and catarrhal, and syphilitic, and abdominal ophthalmia, etc. We no longer use these terms except as they indicate our views in causation; but they have no meaning whatever as descriptive of any special phases of disease in the eye. It is impossible to pronounce in a given case with any better accuracy than good guessing, what is the constitutional condition associated with an inflammatory disease of the eye. It cannot be asserted, except in a vague way, that one case is scrofulous, another rheumatic, and another syphilitic, except by getting information from other symptoms. Of course I admit that weakly patients, and those who are badly nourished or cachectic, will have a type of inflammation differing from that of the robust, but beyond this general statement it is not safe to attempt to refine.

I grant that for successful treatment the constitutional condition must be accurately appreciated, but we learn this by interrogating the system, and not by looking only at the eye.

I want to say something on the subject of sympathetic ophthalmia. Every physician is consulted respecting cases of injury of the eye. All know that instances occur where the remaining eye subsequently is inflamed, and may be lost through an injurious influence exerted upon it by the damaged eye. It is of the highest importance to know first what classes of injuries are likely to exert this pernicious sympathy; and secondly, what are the early signs that it has begun.

The injuries most prone to cause mischief to the second eye are: 1st, when foreign bodies enter and lodge in the organ; 2d, when the eye is badly lacerated, especially in the region just behind the cornea; 3d, when the crystalline lens is dislocated; or 4th, when the iris is extensively caught in a wound or cicatrix. The time when such trouble may begin can be as early as three weeks or six months, or as late as two years or twenty years. The eyeball likely to cause such mischief is one in which attacks of inflammation now and then occur, and, above all, one which is sensitive to slight pressure of the finger. If a damaged eye which has recovered from the first effects of its lesion cannot bear moderate pressure without causing pain, that eyeball or stump ought to come out.

What are the *symptoms* of sympathetic trouble? They are of two general classes; first, those which implicate the general usefulness of the eye; secondly, signs of inflammation of the iris, choroid, optic nerve, and retina. As to the first, the person complains that he cannot use his eye, it easily wearies, it runs water, it is sensitive to light, yet its vision may be perfect. There may be conjunctival hyperæmia, but no other lesion. Unless some clear cause for complaint can be found in special defect of the eye to account for these symptoms, such as astigmatism or far-sightedness, etc., the damaged eye must come out to protect the good one. But a more subtle and dangerous condition is a low form of iritis, called serous iritis, which will not give pain, and not command attention, especially among children and ignorant persons, although it will somewhat impair sight. A more intense degree of inflammation, an irido-choroiditis, may occur, and these are severe forms of lesion which are sure to attract attention. For these patients a grave responsibility must be assumed. In some of them the enucleation of the injured eye seems to excite rather than allay the sympathetic trouble—such is the last scientific utterance on this subject (see Mauthner, *Vorträge*, etc., 1879); and reflection on some cases, in my own experience, inclines me to accept this statement with

respectful attention. For other cases enucleation must be practised at once, and it banishes the dreaded disease as by magic. For the advanced cases enucleation is impotent; it does neither good nor evil. Hence, in a juncture so critical as when a fellow-being asks for counsel as to what is to be done to preserve him from the misery of total blindness, a large experience and skilled observation must be the basis of sound advice. As a practical suggestion it may be said that, when a person receives a severe injury of one eye, and he live at a distance from a good eye surgeon, or if he be ignorant, or a child of ignorant parents, it is safe to take out the damaged eye at once, and thus protect the other from any baleful influence. For those better circumstanced or properly observant of themselves, some discretion may be permitted; but they must be stringently warned to present themselves for inspection on the slightest token of trouble.

One other topic remains before I close. It is not uncommon for cataract in old people to be confounded with glaucoma, and *vice versa*. It is true that cataract is the more frequent disease, but it is not fatal to sight as glaucoma. Now, the latter often seems to the naked eye to be just like cataract. The distinction between them can to some degree be made out by any physician, and is to be found by noting that the eye which has glaucoma is hard and resists the pressure of the finger far more than the normal eye, or than a cataractous eye. Again, the field of vision is invaded and partly cut off, especially on the nasal side, by glaucoma, as does not occur in cataract. How shall this be discovered? Examine each eye by itself, having the other shut. Let the patient look at your eye, and, while he fixes his direct gaze upon you, let him note whether he can see the hand held up at his temporal side, and afterward on his nasal side. On the outer side, the hand should be visible to an extent of almost 90 degrees; on the nasal or medial side the limit of the field of view is from 40 to 45 degrees, being bounded by the height of the nose. Now, in glaucoma, while the direct vision suffers more or less, the lateral vision is also very markedly impaired. Especially does this take place on the nasal side, and to this symptom I invite special attention. By very simple experiment it will be found that absolute blindness exists over a space on the nasal side of the field of vision, in which a cataractous patient will be perfectly able to see light and perhaps also objects. The real diagnosis of glaucoma will need the help of the ophthalmoscope, and that is of no use to the untrained and inexperienced observer. Another point is perhaps worthy of note, viz., that while in glaucoma the pupil is very apt to be smoky, this may be thought to be evidence of cataract; whereas a smoky pupil is the natural condition in eyes of old persons.

I can only ask your attention to the possibility of making the false diagnosis alluded to, and leave the topic to your own reflection.

Gentlemen, I may no longer trespass on your patience. Very much more might be said, and I leave to those who follow me, to indicate what I leave untouched. These suggestions are tendered with much distrust, but with a genuine feeling of good-will and desire to aid in our common work of promoting the happiness and abating the misfortunes of our fellow-beings. This cluster of fruit from the small plot which I cultivate, is placed in your hands as the expression of my fellowship with you, in the husbandry of science and humanity, as well as a testimonial of my most sincere regard. Would that the gift were more worthy of your acceptance!

ON THE RELATION OF SEWER-GAS TO
TYPHOID FEVER.

By GEORGE HAMILTON, M.D.,

PHILADELPHIA.

(A paper read before the College of Physicians of Philadelphia.)

THE subject of the paper for this evening cannot but be regarded as one of much importance, as well in relation to medicine as in reference to the public at large. As you are all aware, the attention of the community, in general, has for a few years past been drawn in an unusual degree to the subject of sewer-gas as an agent in the production of typhoid fever, and recently it has been declared by several writers to be the most potent and common cause, not only of this fever, but also of scarlet fever, and, in a special degree, of diphtheria. As a consequence of these declarations, a feeling of anxiety and alarm has manifested itself, greatly disproportionate to what an unbiassed and calm consideration of the subject will admit, or an examination of the reports of the Board of Health will justify. That those members of our profession who have endeavored, so earnestly and persistently, to impress upon the mind of the public, as well as of the practitioner, that sewer-gas is the most potent and common cause of typhoid fever in Philadelphia, have acted conscientiously, no one need doubt. To their excellent standing in the profession, and to their zeal in promulgating the views alluded to, is, in great measure, due the success that has attended their efforts in this direction. So successful, in fact, have these efforts proven that probably one-half of the profession in this city, and a still larger proportion of the citizens who may have given some attention to this subject, have been induced to accept the views so urgently pressed as a finality. It is, however, to be remembered that very little in opposition to the opinions stated has been attempted, and it may be that the present will prove a futile effort to stem the actual current of professional and popular feeling upon this subject. Nevertheless, we feel quite assured that a large majority of practitioners who have had, at the bedside of patients, the most frequent and abundant opportunities for the study of typhoid fever, will reject the evidence hitherto offered to prove that sewer-gas is the most potent and common cause of typhoid fever in Philadelphia, or elsewhere, as utterly untenable, and as in direct antagonism with the facts and figures pertaining to that malady.

An observation or two, in reference to the more acute aspect of disease as it occurs in the country, compared with what is seen in city practice, may here be admitted, bearing more or less directly upon the subject before us. The late Dr. Joseph Parrish, eminent in citizenship and as a practitioner, when lecturing, in 1830, before a summer class of students upon bilious remittent fever, narrated his sad experience of this disease, as witnessed in consultation with country physicians within a circuit of about seven miles of the city (sometimes in Pennsylvania, at other times in New Jersey), by declaring that, in frequency in proportion to population, and in violence and fatality, it greatly exceeded anything he had ever met with in Philadelphia. The same remark was made by him in regard to dysentery, and was fully verified by the writer when, a few years later, he began practice thirty miles distant from the city. The accounts received from time to time from country physicians regarding the disastrous epidemics of the diseases mentioned, and, in an especial degree, of diphtheria, are doubtless familiar to you.

Some statements, made by the writer during the discussion that followed the delivery of the paper of Dr. Keating upon the relation of sewer-gas to typhoid fever, must here be repeated, as some who are now present may have then been absent. Centreville, my location in the country for more than ten years, was upon the ridge separating the Brandywine and Red Clay Creeks—distant seven miles from Wilmington, seven from Kennet Square, four from Dupont's, and eleven from West Chester. The surrounding country, rolling or hilly, abounded in nearly every direction with springs of fine water. In this rural section began my first bedside experience in typhoid fever, and the occurrence in my practice of four cases of intestinal perforation, in the space of twelve consecutive months, may but too well attest the character of the prevailing epidemic. It was not, however, until after five years' practice in this vicinity that typhoid fever developed itself; the usual form of fever in earlier years of practice having been bilious remittent, which, like the typhoid, at times assumed an epidemic character, and proved nearly as fatal as typhoid, while in other seasons but few cases occurred, the local conditions remaining essentially the same from year to year.

The change from bilious remittent to typhoid fever was, naturally enough, not abrupt, some of the symptoms of the former gradually giving place to those of the latter. In mode of progression there was a close resemblance between them; either disease showing itself upon an elevated plain, on the brow or slope of a hill, or in the vale below, with perhaps a slight preference for the latter; while the mansion of the opulent farmer would, in turn, be visited with the home of the humble cottager.

Two remarkable instances of typhoid fever, mentioned in the discussion before alluded to, cannot, for the reason then assigned, be passed in silence. One occurred in the residence of a wealthy farmer, the family consisting of eight persons, of whom only one, the mother, escaped an attack. Six were severely affected—three of them dangerously—while the seventh, a colored servant, suffered but slightly. Now, the important point in the history of these cases is revealed in the fact that the disease did not originate upon the premises. A son, about nineteen years of age, had been absent several weeks on business in Maryland, forty miles distant from his father's residence, and from thence was brought home sick, and, apparently from contagion; the others were in turn affected, giving rise to an attendance of nearly four months before the final recovery of the last patient. The second instance happened in a family of seven persons, four or five of whom were attacked, the death of a youth of eighteen years resulting from perforation. Here, again, the disease did not originate on the premises: the mother, the first patient, who had been assisting in nursing a relative several miles distant, was brought back to her own home suffering from typhoid fever, contracted apparently from that relative. The number of persons attacked in both of these examples was exceptionally large, yet the disease rarely appeared in a family, even of moderate size, without more than one of its members being affected.

As to the origin of these widely diffused, destructive epidemics, nothing could be said in explanation, except that, as a rule, a warm, moist spring, and, as a sequence, excessive growth of vegetation, followed by a hot, dry summer, appeared to favor the development of typhoid; just as had been noticed in former seasons in regard to bilious fever. In relation to the influence of local conditions, it may be said that in

an old, long cultivated section, changes in these conditions rarely occur, and certainly nothing of this kind did occur that could explain the ravages of fever in one year, and its absence or slight character the next; and hence the physicians of that section, so far as I knew, were nearly of one accord in regarding atmospheric, hygrometric, electric, or telluric conditions as the sources of the presence or absence, and of the violence or mildness, of the epidemic.

On returning to the city, thirty-three years ago, a location for practice was chosen at Sixteenth and Summer streets, and has thus continued ever since. At that remote period, intermittent, remittent, and typhoid fever prevailed to a considerable extent, especially between Broad Street and the Schuylkill. Not one of these types can now be seen so often, in proportion to population, as during the earlier years of my practice in this locality.

Some years after returning to the city, Professor J. K. Mitchell was called to consult with the late Dr. Gebhard and myself in a severe case of typhoid fever near my residence. This was at a period when bilious remittent was being gradually supplanted by typhoid fever. Dr. Mitchell then stated to us that nearly all the cases of this disease seen by him were in consultations upon the suburbs of the city, as in the case in which he met us, for at that time the locality was but a suburb; yet in the suburbs at that period there were but few sewers or cesspools, and, as to water-closets, they were not to be found there; while, on the contrary, in his own vicinity (Eleventh and Walnut streets) they existed in all directions, and yet, as he informed Dr. Gebhard and myself, he scarcely ever saw typhoid fever in the families under his immediate care. Again, the late Dr. Wm. W. Gerhard, prominent as an authority in typhoid fever, informed me, about six years before his death, that he no longer regarded typhoid fever as either so prevalent or so fatal in this city as it had been in former years; that some modification of the disease, from unknown causes, had occurred, just as he had witnessed many years previously in Paris, where typhoid fever in some of the hospitals had gradually changed in character until from a mortality of one in three patients, only one case out of seventeen attacked terminated fatally. With the statements and opinions thus expressed my own observations and experience fully accord.

During thirty-three years of practice in the city, four cases of typhoid fever, occurring in one family, have come under my care; in two or three families two persons in each have been affected; yet, setting these aside, one case only in any family coming under my observation has occurred. This is in striking and most favorable contrast with what, as before stated, often happens in epidemic typhoid in the country, where no sewer gas or obstructed drains are to be found in explanation of this difference. The increase in the number of sewers, water-closets, and cesspools, in Philadelphia, for some years past, has been simply enormous; and consequently the opportunities for contamination of the atmosphere, water, or milk, correspondingly augmented. If (as some have asserted) sewer-gas is the most potent and common cause in the production of typhoid fever, and if so large a proportion of the houses in the city are infected by it, would we not have, in a population of nearly nine hundred thousand inhabitants, cases almost without number, and deaths in proportion, far more than quadruple the average number reported by the Board of Health?

Physicians have long differed in opinion in reference to the conditions under which typhoid fever is

likely to occur, and in regard to the influence exerted by the various agents known, or believed, to play a part in the production of this disease. While many, at the present moment, are disposed to accept the opinion that in an atmosphere contaminated by sewer-gas, or effluvia arising from cesspools, or decaying animal or vegetable matter, is to be found the ostensible cause of the disease; others are more disposed to refer it to the use of milk or water infected by the agents just named, and, in addition, to the consumption of food partially decayed. On the other hand, there are those who, whilst admitting the possibility or probability that certain limited outbreaks of typhoid may be referred to the local causes just named, are fully convinced that the widely spread and fatal epidemics witnessed at times in the country can be explained by no such agencies as those alluded to; neither do we think that a practitioner, who has had the experience of a single season of epidemic typhoid fever in the country, can refer to these agents as the cause of such epidemic, without rejecting the evidence of his own senses.

Dr. James Jackson, of Boston, long before Pettenkofer, in explanation of certain erratic and very restricted outbreaks of typhoid fever, ventured to suggest that, in the absence of any visible agency, some emanation from the soil, obscure as to origin, might account for them. Pettenkofer, however, determined that in proportion to the elevation or depression of the water level in the earth was the greater or less prevalence of typhoid fever, without fixing any limit as to the extent of its influence. When we call to mind that, as before stated, a hot dry summer is, as a rule, the precursor of an unusual amount of fever, either remittent or typhoid, the view of Pettenkofer demands attention and earnest consideration; for, after laborious and protracted researches, he announces, definitely, that in proportion as the water level becomes lower, typhoid fever increases. That many epidemics of the fever appear without the possibility of assigning any special cause in explanation of their origin, is manifest, and no one is more prepared to admit this than the practitioner and medical writer of large experience. Whatever may be the cause or causes of the fever, when once established, contagion, especially when aided by the concurrence of certain indefinable, elemental, and local influences, lends its all-powerful aid in its extension; this, at least, is the opinion of Bretonneau, Trousseau, Louis, Gendron, Chomel, and many other investigators of the disease in France, England, and the United States; among the latter, Drs. Nathan Smith, James Jackson, Elisha Bartlett, and Austin Flint, Sr.

Of the writers quoted, nearly all recognize that very frequently the disease arises spontaneously, and, while some of them admit that a limited number of cases may be due to emanations from sewers or cesspools, others, regarding typhoid fever as specific in character, claim that a specific cause is necessary to develop the disease; and that they find no sufficient evidence of such cause either in the respiration of the effluvia alluded to, or in the consumption of unwholesome food. Trousseau, the medical genius of France, declares "that in Paris, or other large centres of population, it is impossible to determine the origin of the malady, and that this can only be done by physicians who practise in limited spheres, when it can generally be ascertained where the first attack of the disease was noticed." Than this, nothing could be more certain in relation to contagious disease in general; for in the street-car may be seated by your side the washerwoman, whose bundle upon her lap

may contain the clothing of a patient affected with a malignant disease.

When, from time to time, on meeting with physicians of this city who have formerly practised in the country, the inquiry has been made as to the origin of typhoid fever, the answer has been, without exception, that only in an occasional case could even a hypothetical local cause be assigned. The late Dr. Gallagher, of West Philadelphia, once informed me that, from 1839 to 1842, he was nearly broken down in attending to cases of typhoid fever occurring in the fine rural sections four or five miles west of this city. If typhoid is a specific fever, and has as a definite, specific cause, sewer-gas, what can be said in explanation of its great prevalence and fatality at the distance of a few miles only from the city, where no sewer-gas exists? All writers and practitioners, however, do not accept *in toto*, perhaps not at all, the sewer-gas theory, but on the contrary refer to the emanations from decomposed vegetable and animal substances, and from cesspools, as frequent sources of the disease; in addition to which, a third class of observers insist that food, liquid or solid, contaminated by these agents, must be taken into account before a solution of the grand problem, the causation of typhoid fever, can be accomplished. But these various hypothetical or assumed causes have been for years under serious and earnest consideration, yet, so far from solving the difficulty, we are in many respects little farther advanced than when Montaigne, three centuries ago, in his amusingly furious tirade against doctors and their prescriptions, said, quoting the language of Pliny: "That the most important science in use with us, that which has our preservation and our health in charge, is unfortunately the most uncertain, confused, and disturbed by the most frequent changes;" and then, giving utterance to his own thoughts, he exclaimed: "There is no great danger of our being mistaken as to the altitude of the sun, or in the fraction of an astronomical calculation, but here, where it concerns our very existence, it is not wisdom to expose ourselves to the mercy of so many contrary and agitated winds."*

Attempts have often been made to explain away the difficulty of accounting for the extraordinary prevalence and fatality of typhoid fever in the country, as compared with the city, by alleging that the water is, probably, contaminated by the well being too near to where is located the family necessary, or otherwise that the drainage is from the latter to the former. Again, it is said that the effluvia, arising from decayed vegetable matter stowed away in vaults or cellars, are a fruitful source of the disease. That such a condition of things may obtain among families in some of the manufacturing towns of England, or other places in Europe, or in certain localities of this country, may be granted; but that it characterizes any considerable portion of the rural sections that have come under my own notice cannot, in truth, be admitted; and certainly the charge of negligence and improvidence, implied in the above allegation, can have no application to the circle of my former practice in the country, nor to the region adjacent.

A most significant reference must here have place. At the distance of three miles from my location was

situated, upon the Brandywine, the cotton factory of Mr. Wm. Young, employing a large number of hands, of whom probably at least one-half were under my care; and yet, so far as memory serves, only two cases of typhoid fever there ever came under my charge. At the distance of about a mile below are located the immense establishments of the Messrs. Dupont, where thousands of people live in comparative proximity. As my practice did not extend to these works, a note was sent a few weeks ago to Mr. Henry Dupont, asking whether or not typhoid fever prevailed among his employes during the years 1840-1843. The note of Mr. Dupont in reply states that, while of so distant a period his recollection is not clear, his impression is that there were but few cases of typhoid fever at that time among the people, and that they are generally healthy. A note recently received from Dr. Jos. P. Chandler, of Centreville, who has had an extraordinary opportunity of investigating the disease, confirms the impression of Mr. Dupont, as he is well qualified to do from the large practice he has had at the works.

Dr. Chandler also informs me that, with the exception of a few cases of the fever, where it seemed probable that local causes may have given rise to the disease, the rule has held good that its origin is involved in obscurity. This statement is fully justified in the fact that the manufacturing centres, with their closely situated houses, do not suffer, as his letter informs me, in comparison with the rural sections, where the disease will often appear in the best and most favorably situated dwellings, with nothing within or without to explain the cause. Now when we call to mind that, in some seasons, typhoid fever has prevailed extensively on the north and south side of the Brandywine, while the intermediate banks, with their dense population, have suffered but little, is it not worth while to concede, at least, to such a statement, so full of truth and meaning, that measure of thoughtful consideration which its importance merits, and in fact demands? At the present moment, and during the last two or three months, Wilmington has suffered from an unusual amount of typhoid, yet the banks of the Brandywine have had but few cases; and whilst the proverbial generosity of the Messrs. Dupont never flags, when the safety, the health, or the general welfare of their employes is in question, the fact is nevertheless obvious, that the local conditions must, of necessity, be in several points such as in the opinion of many physicians would surely engender an epidemic of typhoid fever, which yet for a long series of years has not occurred.

In the earlier part of this paper it was stated that the reports of the Board of Health of this city did not warrant the anxiety and alarm that exist in relation to sewer-gas, as the chief agent in the production of typhoid fever; and without going into details, a few points only will be adduced in reference to this matter. The reports show that very often the deaths from this disease are more numerous in the winter months than during the hot weather of the summer. For example, in January, February, and December, of 1878, the deaths in the order named, were 34, 32, and 33, whilst in July the deaths were but 23; yet this month, as shown by the record of the last ten years, is the hottest of the year, and consequently is the period when fermentation, decomposition, and putrefaction are most actively engaged in evolving effluvia from animal or vegetable substances. This record of facts and figures may, by some, be regarded as inconceivable and perplexing, yet it finds its counterpart in the country, where during one entire winter the disease was un-

* "Que la science la plus importante qui soit en nostre usage, comme celle qui a charge de nostre conservation et santé, c'est, de malheur, la plus incertaine, la plus troublee, et agitée de plus de changements." Il n'y a pas grand danger de nous mécompter à la hauteur du soleil, ou en la fraction de quelque supputation astronomique; mais ici, où il y va de tout nostre estre, ce n'est pas sagesse de nous abandonner à la mercy de l'agitation de tant de vents contraires."—Montaigne, Essais, Liv. 2, chap. 37, Paris, 1831.

sually prevalent and fatal. Incidentally, it may here be stated that Dr. L. P. Bush, of Wilmington, during that winter, made, at my request, the examination of the body of a young man who died, apparently from perforation, and this was verified by his careful *post-mortem* search. To Dr. Bush, in fact, was I first indebted for the intimation that Dr. J. P. Chandler and myself were probably having to do not any longer with remittent, but with typhoid fever, for his attention had, if I remember, been especially drawn to this change of type by Dr. Wm. W. Gerhard, and the work of Dr. Elisha Bartlett.

Quoting again, after this digression, from the Health Office Reports, we find that in a series of years the weekly deaths from typhoid average but six or eight in a population of nearly nine hundred thousand; and it should be remembered that this includes the deaths in the almshouses, prison, penitentiary, hospitals, house of correction, and all other similar establishments, making at least one-fifth to be deducted from the total reported.

It is only a few weeks ago that, of our vast population, only two deaths from typhoid were reported for the week. When we reflect upon the number of inlets constantly evolving gas, at times very offensive; the thousands of residences, factories, etc., infected with it; the throngs of plumbers and gas-fitters who are daily compelled by their vocation to inhale the gas in no diluted form; is there not cause of rejoicing, rather than of the alarm that prompts to invert a tumbler over a small aperture, or fill a slight crevice in the washstand, with paper or cotton? Quite recently there appeared in the daily papers an account of an excursion through one of the immense sewers of Paris, where the odor is said to be so offensive that it can never be forgotten. Is it not strange that this should be permitted if sewer-gas was there regarded as the chief and common cause of typhoid fever? But sewer-gas is also said by many to be the general cause of diphtheria and scarlet fever. By reference to the New York Board of Health Report, for the week ending January 11, 1879, it appears that 274 cases of scarlet fever, and 65 of diphtheria, were returned, and only 8 of typhoid fever; nevertheless, the logical inference deducible from this statement will probably be contested. The deaths from scarlet fever, for the month ending December 28, 1878, were, by the same report, 238, from diphtheria 101, from typhoid fever 24, showing a fair correspondence with the number of cases returned.

My own experience, and that of most physicians who have had much experience in typhoid fever, shows a larger number of cases and deaths among males than females; yet the latter, more domestic in town or country than the former, are far more exposed to the influence of what are now regarded by many as the almost exclusive agents in the production of the disease. Practitioners and writers are generally in accord that the disease is most common between the ages of fifteen and thirty-five years; it will be found, however, that a very large proportion are between seventeen and twenty-one years, the most fatal, too, of all periods, especially when the patient is large and has grown up rapidly; and it is just at this time that young men are prone to out-door life, even when business does not call.

The readiness of some physicians to attribute to sewer-gas an attack of typhoid, if any smell denoting its presence in a house can be detected, is surprising, when every physician knows that this is only an exceptional event. To get over this difficulty it is now declared in some quarters that, although the smell be

lacking, the gas is present, and capable of producing an attack. This is an unfortunate discovery, if it be a discovery; for it would follow from this, that, after much expense in the effort to banish gas where it was known to exist, from the sense of smell, it might still remain, although imperceptible, and keep the family in painful suspense. But have we any tangible and conclusive proof of this lurking, unforeseen danger, and, if it really exist, is it not remarkable that in the thousands of houses, where the odor is annoyingly perceptible, it appears to do so little mischief? Yet after all there is consolation and hope for the people; for it is announced that typhoid fever, and, as may be supposed, with it diphtheria and scarlet fever, can be stamped out. The whole system of existing sewerage is now discovered to be radically wrong, and it is declared that it ought to be torn out, root and branch. In this announcement the dishonest contractor would surely have the largest share of hope and consolation, were it not that a lynx-eyed, intelligent, and fearless Reform Association confronted him. To this association, in fact, are due the thanks of the community for having unearthed the nefarious acts of more than one contractor, and exposed to the light of day the wretched workmanship and worse material, that they fully believed had been forever concealed from human vision. Let the actual system, then, have justice done it, in material and construction, before entering upon the trial of another, involving the expenditure of untold millions still further to oppress the renter and tax-payer.

But what is to become of the rural population who, without sewer-gas, suffer more from epidemic typhoid fever than the residents of cities? Let them, we shall be told, be more careful in regard to local filth, contaminating both air and water or food. This advice appears to be tendered in all sincerity and charity; but whether the people of any well-ordered farming district in the counties adjacent to the city, where the Quaker element, proverbial for neatness and order, so largely prevails, will receive, with due humility and gratitude, the advice so generously proffered, remains to be seen. Admitting, however, that the charge is in some instances well founded, or indeed that every farm-house in the largest county adjacent to Philadelphia has, within or without, the sources of infection, what would it all amount to, diffused over so large an area, when compared to the limited space on which the city is built, with its sewers, water-closets and cesspools, aggregating, in number, tens of thousands, and many of the latter, too, in close proximity to the dwelling, in an offensive condition, and rendered more so by serving as receptacles for every description of putrefied and putrefactive substance. And, again, has the butcher never any unsalable, perhaps semi-putrefied, meat on hand; has the grocer no decayed vegetables or fruits to dispose of; and have the hueksters nothing of a semi-putrid character to stow away, in barrels or boxes, in cellars or vaults, or to have covered up from sight in a filthy stable-yard or outhouse?

The sources, then, of local contamination would seem to be infinitely more numerous in the city than in the country, yet without discouraging those who promise to stamp out disease. The real difficulty is when an epidemic of a violent and extended character starts up, as it has been known to do, in certain mountainous parts of Virginia and Tennessee, in their almost pristine condition, without the semblance of filth to account for its origin. It is evident then, that whatever cases of typhoid fever may have been traced to sewer-gas, or local contaminations, some other

cause or causes must be sought to account for the frequent and disastrous outbreaks in the rural sections; and this, it is clear, was in the mind of that sagacious observer and logical thinker, Dr. Charles Murchison, when he declared his belief in the origin *de novo* of typhoid fever, placing himself, in this point, upon the platform occupied by all the celebrities named in the earlier part of this paper.

Directing our attention once more to the health of our city, as exhibited by the Board of Health from week to week, we see no rational cause for anxiety or alarm; for while the deaths from pneumonia, for the last five weeks, have been very numerous, exceeding by far the total number caused by typhoid fever, diphtheria and scarlatina, taken together, the city, as to general health, may still be, as it has been for many long years, regarded as one of the most healthy of large cities. In the present Board of Health the people, we believe, may have entire confidence, composed as it is of gentlemen of exalted character, and fully interested in the important and responsible work they have in charge; presided over, too, by a gentleman whose fitness for the post he occupies is acknowledged by every one who has examined the recent annual reports, in the preparation of which he is doubtless aided by the indefatigable Registrar. That nothing will be left undone by the Board for the prevention of disease, so far as that is possible, and for the removal of nuisances, even if not productive of disease, we have full confidence. The circulation of exaggerated reports, in relation to any disease, should be avoided, as the tendency is to engender a degree of anxiety and disquietude, whose only effect is to diminish vital force, and thereby render the system more liable to the influence of a deleterious agent.

TREATMENT OF PERITYPHILITIC ABSCESS BY ASPIRATION.

By H. C. POTTER, M.D.,

PRAIRIE CITY, IOWA.

I was called on the 3d of September last to see J. J. Draper, a robust man of thirty-four years. He said he had been taken sick three days before with vomiting and pain in the stomach; but that the pain had shifted to the right side of the abdomen on the morning of the 3d.

I found him suffering severe pain in the ileo-caecal region. Inspection revealed nothing abnormal. Palpation, however, disclosed a small tumor at this point, deep-seated, and painful on pressure. His temperature was raised considerably above the normal (101.5° F.); pulse 95.

During the following twelve days, while the pulse and temperature remained about the same, a gradual increase in size of the tumor took place, with elevation of the surface. At the end of this time an oval elevation occupied the ileo-caecal region, its apex rising perhaps $\frac{1}{4}$ of an inch above the general surface. At its most prominent point slight fluctuation could be felt on rather firm pressure. On the 13th, fluctuation in tumor more marked, and I resolved to operate for its evacuation.

Accordingly on the 14th I called Dr. C. H. Rawson, of Des Moines, in council. After examination we decided to make an exploration with aspirator. The reservoir being exhausted, the needle was inserted at the apex of the tumor, and at the depth of $1\frac{1}{2}$ inches was felt to pass into the cavity of the abscess. The stop-cock was now turned, and about two ounces of

fetid pus flowed over into the reservoir. The needle was then withdrawn.

In consequence of the apparently complete evacuation effected by the aspirator, we concluded not to operate further, unless subsequent developments should render it necessary. On the following day the condition of patient was greatly improved, and from this time he advanced to convalescence as rapidly as could be expected.

He is now able to perform his usual duties.

The treatment during the course of the disease consisted of opiates and tonics to arrest the symptoms. In conclusion, would note the fact that patient submitted to the operation without the exhibition of an anæsthetic, and that he expressed himself as very much relieved immediately on evacuation of abscess.

ACNE ROSACEA—THIRD DEGREE.

GREAT THICKENING OF THE SKIN OF THE NOSE, WITH DEVELOPMENT OF FLESHY EXCRESCENCES—TREATED BY EXCISION.

By P. A. JEWETT, M.D.,

NEW HAVEN, CONN.

S. C.—, aged 70 years, was the subject of this disease for more than thirty years. It had gradually extended until more than half of the organ had become implicated. The diseased mass exceeded in size that of a large orange, and projected most on the right side, causing the patient to present a somewhat unique appearance.

The operation consisted in the removal of the whole diseased mass, by careful dissection down to the cartilage.

The hemorrhage was not troublesome, being readily controlled by the use of solut. persulph. ferri.

The after-treatment consisted in the application of a solution of permanganate of potass., grains v. to $\frac{3}{4}$ i. of water, at first. This was gradually increased in strength to gr. x. to $\frac{3}{4}$ i. as the growth of the granulations seemed to require. The wound was entirely healed at the end of two weeks, without sear, roughness, or contraction.

In the *MEDICAL RECORD* of August 3, 1878, Prof. Hebra, of Vienna, is reported as having performed a similar operation on two patients. He says, that "in each case he succeeded in forming a very presentable nose, to the great delight of the patient and his own satisfaction." The nose in my case is not only "very presentable," but is as good as the original organ. The patient is very proud of his improved appearance.

NEW HAVEN, CONN., February 3, 1879.

THE PLASTER JACKET.—Dr. R. E. Power sends to the *British Medical Journal* of March 15th some suggestions in regard to the plaster jacket in spinal curvature. To the ordinary mode of application he had found two inconveniences: the friability of the plaster and the tendency of the jacket to become slack. To obviate the first, he moistens the plaster with a thin solution of gelatine. For preventing the loosening of the jacket he uses coarse brown paper instead of the woven shirt. This is immersed in warm water for a few minutes, and then applied to the chest. The plaster is rubbed upon this; then another layer of paper superimposed, and the whole then suitably bandaged. When this jacket dries it does not shrink, and is moreover somewhat elastic.

Progress of Medical Science.

ON THE "PHENOMENON OF THE KNEE," AND ON TENDON-REFLEXES IN CHILDREN.—The researches of Tschervj tend to demonstrate that the sharp contraction of the triceps cruralis, excited by percussion of the ligament of the patella, and known by the name of *phenomenon of the knee*, is not the result of direct irritation of the muscle, but is reflex in character. The centre which presides over the reflex phenomenon, is situated in the rabbit in that portion of the spinal cord which corresponds to the junction of the fifth and sixth lumbar vertebrae, and to the point of origin of the sixth lumbar nerves. When the cord is divided at this level along with the posterior root of the sixth lumbar nerve on one side, the phenomenon of the knee can no longer be produced on that side. It follows that the abolition of the phenomenon of the knee indicates the existence of a very circumscribed lesion at the above point. In ataxics it indicates that the degeneration of the posterior columns has reached that point. On the other hand the persistence of the phenomenon does not exclude the possibility of an alteration in other regions of the cord. The exaggeration of the tendon reflexes in spasmodic spinal paralysis should be ascribed in part to the paralysis of the antagonists.

Prof. Eulenburg has studied the subject of tendon reflexes during the first years of life with the following results: Out of seven children who were examined during the first twenty-four hours after birth, the phenomenon of the knee was very distinct in six, while, on the contrary, the phenomenon of the foot could only be obtained in one. In one boy, thirteen days old, who was suffering from atrophy, the phenomenon of the knee was wanting, but it was present in all the other children between one and four weeks of age who were examined. As a rule it was more marked on one side. It was wanting only in 7 out of 173 infants over one month old; in all of these seven the state of the nutrition was poor and the general health was more or less impaired. On the other hand, in two children suffering from spinal paralysis, the phenomenon of the knee was considerably exaggerated. In children from two to ten years of age, its absence was as exceptional as in the earlier periods of life. It was wanting in a child who was epileptic, as a result of a fall on the head; on the other hand, it was exaggerated in chronic and eclamptic children. It is an interesting fact that, in a case in which Prof. Hueter had resected the crural nerve for obstinate neuralgia, percussion of the patellar ligament was invariably followed by an energetic contraction of the flexor muscles of the leg.

The investigations of Soltmann have proved that the reflex acts are exaggerated, while the excitability of the peripheral nerves is less intense during the first six weeks of life. Hence, since the phenomenon of the knee is observed immediately after birth, it must be admitted that it is a reflex act, and that the contraction of the triceps cruralis which constitutes it, is not the result of direct irritation of the muscles and the motor nerves ramifying in them.—*Gazette Médicale de Paris*, Oct. 5th.

A CASE OF TOTAL EXTIRPATION OF THE UTERUS.—Dr. G. Leopold, of Leipsic, reports a case in which he performed the operation of total extirpation of the uterus, on Freund's plan. The patient was suffering from cancer of the uterus, and the vaginal

walls were not involved in the disease. The operation was performed under the carbolic spray and lasted two and a half hours. In the course of the operation considerable venous hemorrhage took place from the rich venous plexus of one side, which was torn in the application of the lowermost ligature in consequence of the needle pushing the parametrium before it. This was avoided on the other side by making counter-pressure against the point of the needle. Dr. Leopold, from his experience in this case, believes that the venous is more to be feared than the arterial hemorrhage. He recommends that the uterus be not drawn upward too forcibly while applying this ligature, as forcible traction obliterates the vaginal vault, and the needle is then liable to pierce the infiltrated cervix. The peritoneal sutures had to be applied with more haste than was desirable in this case, as the patient had collapsed several times during the operation, chiefly from loss of blood. She came out of the narcosis well, but began to complain of violent pains in the vagina on the same afternoon, and died on the second day from loss of blood and septic peritonitis. At the autopsy the posterior wall of the bladder was found to be the seat of a commencing carcinomatous infiltration. The ovaries were enlarged to threefold their size at the time of the operation, as a result of the congestion caused by the ligatures. They contained numerous extravasations of blood, and the wall of a corpus luteum, that was present in one of them, had been ruptured, permitting the escape of blood into the pelvic cavity. The operation had been performed nine days after a menstrual period.—*Centralblatt f. Gynakologie*, Nov. 9th.

TRACHEOTOMY IN INFANTS UNDER ONE YEAR OF AGE.—As the reported cases of successful tracheotomy performed during the first year of life are but few in number, the two following cases reported by Dr. Elias, of Breslau, are of unusual interest. The first case was that of a delicate girl, ten months old, who was suffering from a severe form of diphtheria. The tonsils, uvula, and posterior wall of the pharynx were covered with a thick membrane. There was marked fetor ex ore, and suffocation was imminent. The improvement after the operation was slow, but on the sixteenth day the canula was permanently removed, and on the twenty-first day the tracheal opening had closed, the voice was pretty clear, and the general condition was excellent. On the following day, however, the child was suddenly seized with violent convulsions, in one of which she died on the same evening. The autopsy showed that the tracheal wound was firmly closed and revealed no abnormality in the respiratory organs or the intestines. From this negative result Dr. Elias concludes that the fatal convulsions had no direct connection with the diphtheria, but that they were probably due to dentition, and favored by the anemia resulting from the severe sickness the child had just passed through.

The second patient was eight months of age, and was suffering from membranous croup. Tracheotomy was performed on the second day of the disease, with immediate relief to the threatening symptoms. The tube was removed permanently on the thirty-third day, and a few days later the wound in the neck was entirely healed. From his experience in these two cases, Dr. Elias warmly advocates an early operation in children under one year of age, when the signs of suffocation are threatening. He recommends the employment of canulae of, at most, from 3-3.3 cm. in length, and 4 mm. in thickness, with a curve of from 1.7-2 cm. radius. The outer canula should have an oval fenestration.

trum. Longer canule irritate unnecessarily the mucous membrane of the trachea. As early as possible the patient should be made to breathe through the larynx; this can be done by removing the inner canula and stopping the external opening of the outer canula with the finger. This manœuvre should be kept up each time until dyspœa sets in. In this way the children will soon become accustomed to breathe through the mouth, and both canule can then be definitely removed without danger.—*Deutsche med. Woch.*, Nov. 9, 1878.

A CASE OF REFLEX VERTIGO FROM STRICTURE OF THE URETHRA.—Dr. Erlenmeyer, of Coblenz, reports the following case: A robust, previously healthy man began to suffer from stiffness and a sense of weight in the left arm, which soon spread to the left leg and then to the right arm. This stiffness was only present at intervals, and was finally associated with severe subjective vertigo. The vertigo occurred also independently of the stiffness of the joints, during micturition, which was rendered difficult by a urethral stricture. In consequence of his suffering, the patient became melancholic and incapable of mental exertion. The objective examination revealed cataract of the stomach and bladder, and increased reflex of the patellar tendons. The patient staggered and complained of vertigo, when he tried to stand or walk with closed eyes. Although the case was very obscure, incipient disease of the central nervous system was diagnosed, and the patient was treated on that supposition, but entirely without result. He finally submitted to treatment for his urethral stricture, and as soon as this was cured the stiffness of the joints and the attacks of vertigo disappeared. The staggering and subjective vertigo, when standing or walking with closed eyes, and the increased reflexes of the patellar tendons, alone persisted.—*Deutsche Med. Woch.*, Nov. 9, 1878.

CARBOLIC ACID POISONING.—Dr. Sonnenburg, of Strassbourg, in a paper published in Vol. IX. of the *Deutsche Zeitschrift für Chir.*, recommended, on experimental grounds, the sulphate of soda as an antidote for carbolic intoxication, and he now states that his subsequent experience has fully confirmed the views expressed in that paper. In all the suspicious cases under his observation, the urine was examined, and whenever the diminution of the sulphates showed that the carbolic acid was beginning to act injuriously, the sulphate of soda was administered; within twenty-four hours, as a rule, the urine threw down a normal precipitate on the addition of chloride of barium, and the suspicious symptoms disappeared.

In the last "Surgical Congress," Prof. Lücke drew attention to the facts that traces of albumen are sometimes found in the urine of patients with open wounds which are dressed with carbolic acid, and that the albumen disappears as recovery progresses, and the dressings are less frequently changed. As the conditions of this albuminuria from carbolic acid are still very slightly known, Dr. Sonnenburg undertook a series of experiments on dogs and rabbits, in which he studied particularly the action of carbolic acid on the kidneys. Strong solutions of the acid were rubbed into extensive portions of the skin of the animal with a stiff brush. Sometimes two or three applications were required, but in a few cases the animals died a few hours after the first application. The results obtained were as follows: After every moderately thorough application of the acid, the sulphates disappeared entirely from the urine. Traces of albumen were only found in the urine of two cases, which

proved very rapidly fatal. The kidneys in all the animals experimented on were markedly hyperamic. In one case, in which death took place after violent convulsions, about six hours after an extensive application of the acid, the hyperamia of the kidneys was unusually great; this case presented also hemorrhages into the cortical substance, and hemorrhagic casts in the convoluted, but more particularly in the straight tubes. The urine found in the bladder at the autopsy also showed traces of blood. From these investigations, it is clear that carbolic acid can be absorbed by the skin, and produce very serious derangements in the kidneys. It is true that such acute poisoning, as occurred in the above case, in which hemorrhages into the renal substance were found, could scarcely occur in men from absorption of carbolic acid through a wound. Still the power of carbolic acid to excite hyperamia, etc., in the kidneys, may become of serious import in cases in which the nutrition and circulation of those organs are impaired by long-standing suppuration; it may then explain the occasional occurrence of albuminuria without any other notable symptoms of poisoning during the treatment of wounds with carbolic acid.—*Centralblatt für Chir.*, No. 45, 1878.

CHANGES IN THE SYMPATHETIC IN A CASE OF PROGRESSIVE PERNICIOUS ANÆMIA.—Dr. Brigidi reports a case of progressive pernicious anæmia in which the autopsy revealed interesting changes in the cœliac plexus, but no fatty change or other lesion in the heart and other viscera. In the fresh state the plexus presented an excessive proliferation of nuclei, so that in many places the nerve-cells were destroyed; in other places these cells seemed pigmented, but were cleared up by the addition of reagents. The blood-vessels were empty. In ganglia, hardened in alcohol, the nerve-cells could only be found in isolated spots; in the greater part of the sections they were replaced by groups of small elements, which resembled nucleoli. From the microscopical appearances, Dr. Brigidi constructs the following chart of the pathological process: The endothelium lining the capsules of the ganglia began to proliferate abnormally, destroyed the nerve-cells by pressure, and formed granulations, some of which assumed a bronzed or brown color, while others underwent fatty degeneration. The further this fat development proceeded, the more the nerve-substance disappeared, until finally, the proliferation of nuclei persisting, the entire nerve-substance was destroyed, and its debris was found dispersed in the newly-formed nuclear growth. The nerve fibres of the ganglia had likewise undergone fatty degeneration. The empty blood-vessels of the ganglia also presented an excessive proliferation and accumulation of the endothelium. Around the ganglia there were thick layers of connective tissue, which was but poorly supplied with nerves.—*Allg. med. Cent.-Zeit.*, No. 98, 1878.

DEATH FROM AN INTRA-UTERINE INJECTION.—At the meeting of the London Obstetrical Society, March 5th, a uterus was shown of a very interesting character. The patient had expelled a vesicular mole six months before. She then suffered from menorrhagia, and was admitted to St. Thomas's Hospital. The hemorrhage continuing, a solution of perchloride of iron was injected. The second syringe-ful was sent into the uterus. The patient died, and on examination iron was detected in the peritoneal cavity.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, April 19, 1879.

TENDON-REFLEX.

THE ankle or foot-clonus (foot-phenomenon of Westphal), produced by irritation of the tendo Achillis, is in many respects similar to the "knee-phenomenon" which we discussed in the preceding number of the Record, and is, in fact, considered identical with it by the majority of neuro-pathologists.

This phenomenon is produced in the following manner: If the foot be abruptly forced into complete flexion by one hand applied to the sole, and the tendo Achillis, which has been necessarily rendered tense by this manœuvre, be smartly tapped with the finger or other small object, such as a percussion hammer, the foot will immediately begin to undergo alternate movements of flexion and extension, due to alternate contraction and relaxation of the anterior tibial and calf muscles. These movements will continue as long as firm pressure is maintained by the hand which is applied to the sole of the foot, or until the muscles of the leg have become exhausted. When the phenomenon is well marked it may also be produced by mere forcible flexion of the foot without resorting to the additional stimulation of the tendo Achillis, and, in extreme cases, the mere weight of the bed-clothes resting upon the tips of the toes may cause violent movements in the limb. The initial contraction can also be frequently developed by tapping the anterior tibial muscles, and this is a very significant fact, since this procedure can have very little effect upon the tension of the tendon.

After careful investigation of a large number of cases, Dr. Gowers found that from five to seven contractions occur per second, the average number being 6.1.

Many of the French neurologists, and notably Joffroy, have maintained the opinion that the ankle-clonus is a simple cutaneous reflex, similar to the spinal epilepsy which was first described by Brown-Séquard nearly thirty years ago. According to Erb,

many of the cases of so-called spinal epilepsy are due to the fact that when the sole of the foot is irritated by tickling or pinching, the foot is immediately drawn up into active dorsal flexion, the tendo Achillis is thereby rendered more tense, and the tremulous movements produced in the leg and thigh (and which are sometimes communicated to the other limb) are, therefore, similar to those observed in foot-clonus. In addition, it has been shown that foot-clonus may be produced, even if the cutaneous sensibility of the lower limbs is lost, and, on the other hand, the reflex excitability from stimulation of the skin may be increased, though the foot-clonus may, nevertheless, be wanting.

As in the tendon-reflexes to which we referred in the preceding article on this subject, foot-clonus is indirectly due to the increased tension produced in the calf-muscles by the increase of the tension of the tendo Achillis. The simple fact that, as we have previously mentioned, a tap on the anterior tibial group of muscles will, in certain cases, produce ankle-clonus, if the foot be simultaneously held in dorsal-flexion, although tapping the tibia itself is not followed by a similar phenomenon, is sufficient evidence that mere tension of the tendon, without implication of the muscles, is not the essential cause of the development of ankle-clonus.

It would appear, therefore, that ankle-clonus is, in most respects, identical with the patellar reflex or "knee-phenomenon." Gowers has shown, however, that the two sets of phenomena differ in certain fundamental characteristics. The measurements of this author, by means of the myograph, have demonstrated conclusively that the interval which elapses between tapping the tendo Achillis and the appearance of the first contraction in the muscles of the calf varies from .025—.04 of a second. This period is entirely insufficient for the production of a reflex act, the time required for the development of the latter varying from .10—.11 of a second (nearly three times as long as the former period).

Ankle-clonus must therefore be regarded as the effect of direct stimulation of the muscles (anterior tibial or calf groups), which are in a condition of exaggerated irritability.

According to Gowers, however, this exaggerated irritability of the muscles may itself be a reflex effect of the tension produced in the fibres by the passive flexion of the foot. This opinion is substantiated, to a certain extent, by the fact that the phenomenon is not produced immediately after flexion of the foot, but that a sufficient period elapses (as shown by the tracings of the myograph) for the development of a spinal reflex.

Dr. Gowers calls attention to a very interesting physiological application of this view. During the act of walking the contraction of the calf muscles (raising the heel) always follows the increased tension

which has been called forth in these muscles by the contraction of the anterior tibial group of muscles (raising the toes), and Gowers believes that a physiological reflex between these two sets of phenomena is probably developed in early life when the child is beginning to walk.

Ankle-clonus is frequently observed in health, but not with the same regularity as the patellar reflex.

The chief clinical interest hitherto attached to ankle-clonus, refers to its occurrence in lateral sclerosis, in which disease it is developed to an excessive degree.

Unfortunately, however, the patellar-reflex has hitherto usurped the greatest amount of attention among the so-called tendon-reflexes (ankle-clonus having been regarded as identical with it), and, as a natural consequence, while we have made some advances with regard to the physiology of ankle-clonus, its clinical bearings have been almost entirely disregarded.

THE REPORT ON THE STATE CHARITIES.

THE recent report to the Comptroller upon our State Charities has deservedly attracted much attention and is likely to invite a long discussion. It bears especially upon the financial management of the various State institutions, and that part which relates to Insane Asylums, therefore, will be a fitting complement to the proposed investigation into the medical side of the question. The present report is one step at least in the right direction.

Mr. Apgar, its author, has evidently done his work with care and honesty. He gives, perhaps naturally, a rather *ex parte* statement of the case, and one would judge that he had never had any great experience previously with the institutions examined. Nevertheless his main conclusions are so well supported with statistics that they cannot be disproved.

He shows what we have before maintained, that there is much unnecessary and injudicious expenditure in the management of Insane Asylums, and he refers to one of the causes upon which we have especially insisted, namely, that of constructing large asylums, and then weighting one person with both the medical and business management. There can be no stronger illustration of the grotesque character of the present palace-asylum system than that furnished in Dutchess County. The per capita cost of private dwellings there is \$386, while that of the insane asylum is nearly nine times as much. In other words, the average tax-payer lives in the modest accommodations of a cottage, while the lunatic vegetates amidst the architectural splendors of a building that cost a million and a half dollars.

Mr. Apgar endeavors to show, amongst other things, that while the expense per capita in insane asylums has increased, the per cent. of cures has actually diminished, and that thus our fine buildings, our advanced therapeutical methods, and our special pathological investigations have been of no practical value.

We are inclined to distrust the figures which lead to this conclusion. In determining changes in the per cent. of cures there are many elements to be considered, and we must have evidence that these have not been overlooked before believing that there has been no advance in the therapeutics of insanity during the last twenty years. However, there is certainly an apparent decrease in the number of patients cured, and this fact is held up to show that a lunatic has as good a chance of recovery on \$3.71 a week, the cost of support at Northampton, Mass., as on \$5.00, the cost at Utica, N. Y.

The report suggests that the carelessness and extravagance shown can be remedied by obliging itemized estimates to be submitted regularly to the State Board of Charities, who will examine into their character before submitting them to the Comptroller. Without going into detail, the plan suggested appears to be simple and sufficient.

The report, then, in brief, shows that there is extravagant expenditure without a corresponding increase in efficiency, and plans for securing more rigid economy are strongly recommended as both practicable and necessary. We hope that such may be initiated, but we would not have our legislators forget that the reform should not be in the interest of economy alone. We have more than two thousand insane persons who fail to get even the advantages of a good asylum. It will neither be human nor wise to neglect these; and simply securing a reduction in board of two dollars a week will constitute but a small part of a much-needed general reform.

THE DINNER TO PROF. S. D. GROSS.

THE complimentary dinner recently given to Professor Gross, of Philadelphia, was an event which will long be remembered by the participants. The occasion was an unusual one, not only in regard to the commemoration of half a century of professional work, but on account of a singular unanimity of feeling of the representative men of Philadelphia and elsewhere, in showing honor to the distinguished guest. To very few indeed is allotted the privilege of active professional life for so long a period, and to still fewer is the gratification allowed of hearing on the eve of a life thus spent in the service of humanity, the plaudits of one's peers, the commendations of those who are best qualified to judge of the merits of one's work. The speakers vied with each other in their expressions of kindly personal feeling, in their appreciation of the labors of the faithful servant of science, and in their good wishes for even greater usefulness.

Prof. D. Hayes Agnew, in his eloquent address, gave the keynote to the sentiment of all present, that of respect and love for the renowned professor. The same sentiments were repeated in the brilliant speeches of Yandell of Kentucky, of Rogers of Philadelphia,

Post of New York, Silliman of New Haven, and Norris of the Army.

The distinguished gentlemen from the different parts of the country who were unable to attend, sent their congratulations by letter and telegram, and helped to make the affair one of the memorable ones of the period.

THE PLYMOUTH AND YELLOW FEVER.

It is reported that the ship Plymouth, U. S. N., which had yellow fever on her a year ago, and came North, and was emptied, fumigated, and otherwise cleansed, and laid up in Boston through the entire winter to freeze out the fever poison, sailed a few weeks ago for the West Indies, and, when off Bermuda, before touching at any port, had yellow fever break out. How does this alleged fact agree with the belief that the fever poison is destroyed by very low temperature?

It is said that erysipelas occurred, during a China cruise, in the U. S. ship Colorado, from 1870 to 1873. The vessel had had erysipelas on her in 1866, after which she had lain four winters in Portsmouth, N. H., dismantled. She had been repainted, etc., from end to end, for the China cruise. On the latter "they could not cut a finger off in the sick bay, or leave a man in the sick bay with a contusion of the skin, without erysipelas breaking out." They had to treat all such cases in quarters, or at the apothecary's rooms.

Has this fact any bearing on the use of old buildings for hospital purposes, or old hospitals for hotel purposes?

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 6, 1879.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

SECTIONS OF THE BRAIN.

DR. JOHN C. DALTON exhibited several sections of the brain prepared in a manner to which the attention of the readers of the RECORD has already been directed. (See RECORD for Feb. 15, 1879, p. 157.)

CENTRUM OVALE.

In the course of the remarks made by Dr. Dalton, while describing the sections presented, he stated that the *centrum ovale* as seen represented in the books did not exist, and was a picture of the imagination. The reason was that the corpus callosum instead of being a plane was an arched commissure, and it was impossible to make sections which would show what the books illustrated.

ASYMMETRY OF THE BRAIN.

Again, he had not seen a brain which was symmetrical.

With reference to the last point the PRESIDENT re-

marked that, several years ago, while conversing with an eminent English obstetrician at a dinner party in London, he suggested that observations be made with reference to the symmetry of the fetal head, believing that the results might have an important bearing upon the question of the mechanism of labor. That gentleman began the observation, had taken models of a large number of fetal heads, and had demonstrated most conclusively that the fetal head was not symmetrical.

EYE TROUBLES IN GENERAL PRACTICE.

DR. HENRY D. NOYES then read a practical and interesting paper on the above subject (see p. 361).

The paper being before the Academy for discussion, DR. H. KNAPP remarked that he agreed essentially with the author of the paper upon nearly all of the points brought forward, and would only add a few suggestions relating to topics of the most practical interest.

OPHTHALMIA NEONATORUM—ACUTE TRACHOMA—EERINE.

One of the most important affections which the general practitioner was called upon to treat was ophthalmia neonatorum, and hence he had found principles followed which were not exactly what he had regarded best in the treatment of the disease. First, with reference to bandaging such eyes. In cases of blennorrhœa, gonorrhœal ophthalmia, diphtheritic or from granulations, he regarded it as decidedly harmful to bandage the eyes in any shape or form. He was convinced that the affections of the cornea, which were of the most serious consequence, associated with these severe conjunctival inflammations, were mainly due to mechanical injury; that is, to the immediate effect of contact between the surface of the cornea and the inflamed surface of the conjunctiva. In granulations, especially of the acute form, that could be plainly proven, and when such eyes were forced to be kept open, improvement was at once manifest.

Dr. Knapp thought it was not necessary to apply any caustic in the first stage of the ophthalmia of the new-born. He thought it was injurious to use nitrate of silver stronger than *three grains* to the ounce of water, if employed at all, and that the five-grain solution was sufficiently strong for the entire treatment. He believed it was of the greatest importance to use cold applications, certainly in blennorrhœa, gonorrhœa, diphtheria, and also in the rare cases of acute trachoma. The applications in some cases, for instance in diphtheria, should be made night and day, and the nurse should devote the entire time to the care of such a patient. In making the applications care should be taken to open the eyelids, and to carefully wash the secretion away from the inside. That should be done at least every half hour, perhaps as often as every fifteen minutes. The secretion itself was corrosive, would produce a sore upon any surface similar to the one from which it was taken, and in the same way it acted upon the cornea. Afterward, when there was proliferation of the mucous membrane and a profuse creamy discharge, nitrate of silver was the proper remedy to be employed. In the first stage he would abstain from its use altogether, or use it only in weak solution.

There were some cases of acute conjunctival trouble which were perplexing even to experts. In those cases the conjunctiva was intensely swollen and œdematous, perhaps there was but little secretion, and that was by no means purulent. He had always treated such

cases with cold applications, and in a majority of instances they were well borne. Sometimes, if the disease was not intense, warm applications did good, and were recommended by Alt; but those were the milder cases. In the more severe cases which were benefited by the use of cold, the condition in the course of four or five days would disappear in another catarrhal conjunctivitis, and at the end of three or four weeks a crop of granulations would be formed. The case then was certainly one of *acute trachoma*, and before the acute stage had passed he thought it injurious to apply caustics. Cleansing, and the use of cold was the proper treatment.

When the time arrived for the use of astringents and caustics the strength of the solution should be proportionate to the swelling of the mucous membrane, and the copiousness of the discharge. He rarely resorted to division of the outer commissure, and did it chiefly for the relief of obstinate cases of spasm. He thought that perhaps the operation was performed too frequently. He also believed that slitting the cornea was done a little too frequently. The antiseptic treatment of these diseases, as practised in Europe, certainly yielded excellent results, yet he was not quite certain but that thorough cleanliness without bandaging might prove equally successful. There was one remedy which exerted a decided influence upon many of these processes, and that was *eserine*; not employed as an antiseptic, but as a remedy to *reduce tension*. He employed it in solution, grs. iv. to the $\frac{3}{4}$ i. of water; its action was manifested sooner and continued longer than that of atropine used of the same strength, but whether it had the same tendency to irritate the conjunctiva he was not prepared to say.

SYMPATHETIC OPHTHALMIA.

According to an authority to whom Dr. Noyes had referred, the tenderness in the eye was most pronounced in the upper ciliary region, and strange to say the tenderness would commence in the other eye in the same region. When, therefore, there was tenderness in the upper ciliary region, as well as in other parts of the eye, and the same condition existed in the other eye, it was probable that sympathetic trouble would be developed.

SEROUS IRITIS.

The serous iritis he regarded as the least dangerous, and was so without enucleation or operation upon the other eye. It would almost always get well.

ESERINE—ASTHENOPIA.

Dr. C. S. BULL emphasized the use of *eserine* in the treatment of suppurative troubles in the cornea. He had been pleased with its effects, not as an antiseptic, but as a relaxer of intra-ocular tension and as a queller of pain which would not yield to atropine. He also referred to the relation between asthenopia, or failing vision, double vision, vertigo, nausea, and headache, and uterine disease. Dr. Swanzy, of Dublin, had met with fifteen or twenty such cases in which there was no error in refraction, and by proper treatment of the uterine disease the eye symptoms were ameliorated, and in many they disappeared.

PRESBYOPIA — ASTHENOPIA — STRABISMUS—HYPERMETROPIA.

Dr. O. D. POMEROY referred to the use of presbyopic glasses. He recommended that convex glasses should be used by those who had the slightest difficulty in reading fine print, providing they were able to relax the accommodation.

*With reference to the treatment of asthenopia the patient should try to relax accommodation and should avoid excessive fatigue. "The eye should be rested before it became tired."

With reference to strabismus he had noticed that there was usually a disposition to relapse. But if he found far-sightedness he employed glasses to be worn constantly, such as were indicated by ophthalmic examination. The glasses might make the patient near-sighted, but it was the only way in which he had been able to prevent the eye from turning inward.

He was inclined to believe that slight hypermetropia was not an abnormal condition.

GLAUCOMA—ASTHENOPIA.

Dr. D. WEBSTER remarked that the presence of glaucoma was too frequently overlooked by the general practitioner. In acute glaucoma it was far more dangerous to make a mistake in diagnosis than in the chronic form of the disease. Acute glaucoma was usually mistaken for neuralgia. He then referred to two cases in which the glaucoma was overlooked; the supposed neuralgia was treated by opium, the opium habit was acquired, and the disease progressed to a point at which sight could not be restored by an operation.

SYMPTOMS OF ACUTE GLAUCOMA.

Acute glaucoma should be recognized by the general practitioner, and the points in diagnosis were the following: Comparatively sudden loss of vision within a few hours, a day or a week; great redness of the eyeball; great pain in and about the eyeball; increase of tension, and dilatation of pupil. There was no other disease which produced those symptoms, and an iridectomy done within a few days almost inevitably saved the eye.

In acute glaucoma, supervening upon the chronic, iridectomy would restore the vision to what it was before the attack. He thought all ophthalmologists saw cases in which eyes could have been saved if iridectomy had been performed for *acute glaucoma*.

With reference to asthenopia, Dr. Webster referred to a case which had been treated one or two years by four skilful physicians for nasal catarrh. The symptoms of which the clerk complained were a sense of pressure at the root of the nose and inner corner of the eyes, a feeling of dulness in his forehead, and he found it hard work to do mental labor; there was no pain. On examination without atropine the eyes were found to be normal. Atropine was introduced into both eyes, and at the end of an hour they were found to be hypermetropic $\frac{1}{2}$; vision $\frac{3}{8}$. After the return of the accommodation he accepted +24 with each eye. Those strong convex glasses were prescribed, and it was not long before all his symptoms disappeared.

CONJUNCTIVITIS—CANTHOPLASTY—FOREIGN BODIES IN THE CORNEA—DOUBLE VISION PRODUCED BY STRABISMUS—RELATION OF THE IRIS TO THE CRYSTALLINE LENS.

Dr. DE ROSSET thought it very important to make an accurate diagnosis of what appeared to be trifling affections of the eye. Cleanliness and the application of warm water would cure almost any case of pure inflammation of the conjunctiva, and yet such cases would stand almost any kind of mild astringent treatment. There were cases in which there was such severe pressure upon the eyeball that the cornea was kept soaked with the discharge from the conjunctiva, and it was important that such pressure should be removed. To accomplish that he divided

the outer commissure. Dr. De Rosset then referred to the irritation which might be set up by a very small foreign body lodged in the cornea, and which very often escaped the notice of the general practitioner. He also referred to double vision produced by very slight degree of strabismus in little children, a fact not infrequently overlooked by the general practitioner, and therefore the double vision became an alarming symptom. Dr. Noyes had spoken of the iris as always lying upon the lens, but he believed that it retired from the lens, because he had seen dilatation to such an extent that the pupillary area was larger than the diameter of any lens which the eye could contain.

Dr. NOYES, in closing the discussion, remarked that he had simply spoken of the treatment of conjunctival disease in its later stage, and that he was pleased with the remarks made by Dr. Knapp because the subject was thereby made symmetrical. In addition, he referred to keratitis occurring in young children. These remarks have been placed in the body of the paper.

The Academy then adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, March 26, 1879.

DR. E. L. KEYES, PRESIDENT, IN THE CHAIR.

THROMBOSIS OF PRIMITIVE ILIAC ARTERY.

Dr. POST presented a specimen of thrombosis of the primitive iliac artery, which had been removed from the patient whose gangrenous leg was exhibited at the previous meeting. The patient died two days after the operation. The thrombosis completely plugged the primitive iliac and extended upward into the aorta, several inches above the bifurcation, but only partially obliterating that vessel. The plug also extended into the femoral and its branches. Whether the thrombosis originated in arteritis or in calcification of the arteries, it was impossible to say.

RESECTION OF ANKLE-JOINT.

Dr. Post also presented the lower extremities of the tibia and fibula which he had removed the Thursday previous by exsection. The patient, aged thirty years, was admitted into the Presbyterian Hospital, during the service of Dr. Shradly, with a compound complicated fracture of the lower extremities of the tibia and fibula. The patient was admitted on the third day after the accident, the parts being in a swollen and inflamed condition. The wound was cleansed with solution of carbolic acid, and also dressed with the same, the parts being kept in as good position as was possible. In the course of two or three days afterward erysipelas developed, and the patient was transferred to the hut. Free incisions were made in the soft parts, evacuating quantities of broken-down material. In the meantime the soft parts over the internal malleolus had sloughed, exposing the bone to the extent of several inches. The lower fragment, became loose in the course of the following month and was removed by Dr. Shradly. During the months which passed since that time the parts had been very nearly *in statu quo*, the lower end of upper fragment presenting itself in the wound, and the ankle-joint remaining open and discharging pus. It was supposed that the bone being necrosed would separate in due time. Recently, on examining the part and finding no tendency toward separation, and concluding that there

was no indication for longer delay, Langenbeck's operation for sub-periosteal excision of ankle-joint was performed. The bones were sawed off an inch and a half above their lower extremities. Neither tendinous sheath, nerve or vessel in the neighborhood was injured during the operation. After the removal of the ends of the tibia and fibula it was found that the upper part of the astragalus was softened. That portion of the bone was accordingly removed by the ring-scraper. The limb was then placed on a plaster apparatus, free drainage being established by means of fenestra appropriately placed.

ANTISEPTIC DRESSINGS IN COMPOUND FRACTURE.

Dr. HOWE asked if antiseptic dressings were used in this case when the fracture was admitted to the hospital.

Dr. SHRADLY answered in the negative. In his opinion, too much time had elapsed from the receipt of the injury to allow of any benefit from the full antiseptic treatment. However, the wound was kept clean, drainage was established, and carbolic lotion was freely applied.

Dr. Howe referred to a case of compound fracture of the ankle-joint which was admitted to St. Francis' Hospital. In that case the full antiseptic method was used immediately after the accident, and the case progressed without an unfavorable symptom.

Dr. KEYES referred to a similar case treated within four hours after the accident, and in which the result was equally satisfactory.

Dr. Howe exhibited a specimen, consisting of the lower ends of tibia and fibula, which he had removed by exsection under Lister.

In conclusion, Dr. Howe remarked that there was no comparison to be made between the advantages of the Lister method with the other methods of dressing wounds.

POISONING BY CARBOLIC ACID—INJECTION INTO AN ABSCESS.

In this connection Dr. Post related the following case of poisoning by carbolic acid:

A boy about five years of age was brought to the clinic of Dr. Post with a subacute abscess in the gluteal region, connected with old disease of the hip-joint. For a week or two before that time the patient had suffered from severe pain in the part. Fluctuation being discovered, Dr. Post made an incision, evacuating two or three ounces of pus. The cavity thus left was injected with a solution of carbolic acid, according to the method advised by Mr. Callender of London. Three injections were used each time, the contents of the sac being pressed out. A drainage tube was then introduced, and a compress and bandage applied. The child was left in the adjoining room at the close of the clinic. Nothing was noticed in the condition of its pulse or respiration to indicate anything unusual. During the same afternoon Dr. Post was summoned to the college to see the child who was said to be dying. It was discovered apparently asleep, some time after the clinic, by the clerk of the college. The latter not being able to arouse the patient, sent for Prof. Weisse, who was in the building at the time. Dr. Weisse, on examining the case, found the radial pulse absent, the skin pale, cold and damp, the respiration short and hurried, and over a hundred per minute. He immediately administered a hypodermic injection of twenty-five minims of brandy. The patient rallied but slightly from this. The pupils being contracted to the size of mere pin-holes, Dr. Weisse administered a hypodermic injection of five

drops of extract of belladonna, which he followed by another injection in five minutes afterward. The pupils then became extremely dilated, the pulse was distinctly perceptible at the wrist, the respiration from over a hundred per minute came down to seventy. In this condition the patient was sent to Bellevue Hospital, where he has continued to improve. Dr. Post thought that the case was one of carbolic acid poisoning.

NOVEL ARTERIAL DISTRIBUTION OF ARTERIES AT BASE OF SKULL—BUT ONE INTERNAL CAROTID ARTERY.

Dr. WYETH presented an injected specimen of the arterial arrangement, at the base of the brain, in a man aged thirty-five years, who had but one internal carotid artery. The right common carotid was present and normal. The left common carotid, about half the ordinary size, sprang from the arch of the aorta as usual, and terminated in the distribution of the left external carotid. There was no carotid canal on this side.

The right internal carotid divided into the anterior and middle cerebral, and gave off a large posterior communicating branch, which joined with the basilar. From this right (and *only*) posterior communicating branch the right posterior cerebral was derived. The right anterior cerebral quite large, divided into three branches, one of which crossed underneath the corpus callosum to the right anterior lobe of the brain. The basilar gave origin to a large trunk which passed obliquely forward and to the left, giving off in succession from behind forward the left posterior choroid, posterior cerebral, anterior choroid, and left middle cerebral which pursued its usual course along the fissure of Sylvius. From this last vessel a very small branch about two centimetres long crossed obliquely to the right, to join the right anterior cerebral. This was the substitute for the anterior communicating. Dr. Wyeth stated that the absence of the internal carotid was an exceedingly rare occurrence. In one hundred and twenty-one consecutive dissections he had made of the surgical triangles of the neck, this was the only case he had seen in which he had failed to find this abnormal arrangement in a large number of other dissections, of which no notes were made. Only two other cases are recorded. *Koberstein* states he had seen a skull in some European Museum with only one carotid canal. Dr. Eugene Pengnet, of New York, reports the other case in an operation performed by him in 1876. [See *MED. RECORD*, Vol. XI., 1876.] The skull and specimen are contributions by Dr. Wyeth to the Wood Museum of Bellevue Hospital.

Dr. FOREST presented a heart removed from an infant four months old, who had died without any symptoms which might lead to a diagnosis. At the autopsy the organ contained an organized clot in the right ventricle. The brain was not examined. In answer to a question, he stated that the foramen of Botal was not patulous.

Dr. FLINT thought that death was probably induced by embolism of pulmonary artery. The Society then went into Executive Session.

THE PLAGUE.—There have been no new cases within the infected area on the Lower Volga since February 9th, and the rigid quarantine that has been preserved is being somewhat relaxed. Sporadic cases of what is called the plague still appear in various parts of the country. Dr. Botkine takes the ground that these are genuine cases, and that the disease is now milder than it was in former epidemics.

Correspondence.

THE COMPLIMENTARY DINNER TO DR. S. D. GROSS.

(Special Correspondence.)

PHILADELPHIA, April 12, 1879.

THE complimentary dinner tendered to Prof. Samuel D. Gross, in commemoration of his fifty-first year in the practice of surgery, took place on Thursday evening, April 10th, at St. George's Hotel, southwest corner of Broad and Walnut streets, Philadelphia. The original plan had been that the dinner should be held at the Union League Club, but the accommodations not proving sufficient for the number of guests expected, the location was changed to the St. George Hotel. The large dining-room of the hotel was richly decorated with plants and flowers. The music was furnished by Carl Sentsz's orchestra.

The subscriptions to the dinner (\$10 each) were limited to one hundred of Prof. Gross's professional friends in Philadelphia. Among the invited guests present were Professors Lewis A. Sayre, James R. Wood, Austin Flint, Sr., Austin Flint, Jr., and Alfred C. Post, and Drs. George F. Shrady, Wm. Bozeman, and M. J. Asch, of New York City; Drs. Van Bibber and Allen P. Smith, of Baltimore; Surgeons Basil Norris and George Otis, U. S. A., of Washington; Prof. Benjamin Silliman, of Yale College; Prof. David W. Yandell, of the University of Louisville, Dr. Gross's successor in the chair of surgery in that institution; Prof. Theophilus Parvin, of Indiana; Dr. Jamar, of Maryland; Dr. Bowen, of New Jersey; Dr. Cardeza, of Delaware; Dr. R. B. Cole, of California; Dr. Traill Green, of Easton, Pa.; Drs. Helsby, Lyon, and Crawford, of Williamsport, Pa.; Dr. Given, of Clifton, Pa.; Dr. Kerlin, of Media, Pa.; Dr. Herr, of Lancaster; Drs. Craig and Sincawearer, of Columbia, Pa.; Dr. Bland, of Pottsville, Pa.; and Dr. Anderson, of Ardmore, Pa. Among the prominent Philadelphia physicians present were Profs. Robert E. Rogers, Ellislie Wallace, Joseph Panoast, J. Aitken Meigs, William Thomson, and J. M. Da Costa, of Jefferson Medical College; Profs. D. Hayes Agnew, James Tyson, Wm. Goodell, and Harrison Allen, of the University of Pennsylvania; and Drs. S. W. Gross, S. Weir Mitchell, Thomas Kirkbride, Ellwood Wilson, Richard J. Levis, Thomas G. Morton, J. Ewing Mears, Albert H. Smith, E. B. Gardette, Addinell Hewson, John H. Brinton, John H. Packard, and Andrew H. Nesinger.

Dr. David Yandell came from his Kentucky home loaded down with flattering messages from Dr. Gross's friends in Louisville. President Lyon, of the Detroit Academy of Medicine, sent the following:

Dr. S. D. Gross, *Philadelphia*:

The Detroit Academy of Medicine send hearty congratulations on the occasion of this jubilee in your professional life. May years of work crown with new honors one of whom America is justly proud.

A. B. LYON, *President D. A. M.*

Other congratulatory messages were read from Professors Oliver Wendell Holmes and Nathaniel Bowditch, and Dr. Horatio Storer, of Boston; from Professors Wm. H. Van Buren, Fordyce Barker, Willard Parker, Frank Hastings Hamilton, and Henry B. Sands, of New York City; from Surgeon-General Barnes and Surgeon Billings, U. S. A., of Washington; from Drs. Chaillé and Richardson, of New Or-

leans; from Prof. Christopher Johnson, of Baltimore; from Prof. Cabell, of the University of Virginia; from Prof. N. S. Davis, of Chicago; from Professors Hogden and Gregory, of St. Louis, and from Dr. Kinlock, of Charleston, S. C.

Prof. Gross sat at the head of the table, with Prof. Agnew, the presiding officer of the evening, on his left, and Prof. Austin Flint, Sr., on his right. The congratulatory address to Dr. Gross, the first event on the programme, was delivered by Dr. Agnew, who, as he sat down, touched Dr. Gross on the shoulder and said: "Allow me, in the name of your professional friends, to pin this token on the lapel of your coat." It was a gold medal, set with diamonds and brilliants, and bearing on its reverse this inscription:

"Presented to Dr. S. D. Gross by his medical friends, in commemoration of his fifty-first year in the profession, April 10, 1879."

Dr. Gross responded as follows:

"In rising to respond to the toast offered by the distinguished chairman, I feel deeply oppressed by what Dr. Rush has so well described as 'suffocated excitement.' You need not be assured how much I appreciate the honor conferred by the occasion and by this warm reception. The sentiments embodied in the toast touch my heart, and I should indeed be dead to all the finer feelings of my nature if I did not tender you my most cordial and respectful acknowledgments. It is no light compliment to be in such a presence, or to be the guest of such a company. To merit the approbation of my professional brethren and of good men generally has ever been my highest ambition, as it must be of every honest and virtuous citizen. The offer of a public dinner, extended to me a few weeks ago by a committee of my professional friends, took me completely by surprise, and would probably have been promptly declined if it had not been accompanied by such kind and flattering words as at once to satisfy me that they came from the heart. The commendations which you have bestowed upon my private character and public services as a practitioner and teacher of surgery are measured, I am conscious, rather by your own generous feelings than by any deserts of mine. Whatever value those services may possess, it is no ordinary consolation to me to know that they are appreciated by men among whom I have lived for nearly a quarter of a century, with many of whom I have been brought into frequent contact in various relations of life—often, indeed, under circumstances of a most trying kind—with some of whom I have been officially associated, and with none of whom, thanks be to God, I have ever had one word of misunderstanding.

"It is not a pleasant thing to speak of oneself, but there are a few circumstances in the history of my uneventful life to which I may perhaps be pardoned for referring upon this occasion. I have grown old in the profession, as pupil and practitioner for fifty-four years, my graduation dating back to March, 1828. A little over one month ago I closed my thirty-ninth course of lectures on surgery. If to these thirty-nine years be added two years spent as demonstrator of anatomy in the Medical College of Ohio, and four years passed in the medical department of the Cincinnati College as professor of pathological anatomy, it will be perceived that my life as a public teacher extends over a period of forty-five years. During all this time it has been my good fortune to miss few lectures, either from sickness or any other cause. If my teaching has not always been of the best quality it has been as good as I knew how to make it. Whatever estimate may have been placed upon it by those who listened

to it I can solemnly declare that it has always been earnest and conscientious, with an eye single to the interests of my pupils, the truths of medical science, and the honor and dignity of the profession. On no occasion have I entered the amphitheatre without due preparation. One of the great objects of my early professional life was to qualify myself for the occupation of a public teacher. This idea, which haunted me as I sat upon the hard benches of my alma mater, like the demon of Socrates, gave me no rest day or night. My first effort in this direction was made in this city, at the Franklin Institute, in the spring of 1830, the subject being general anatomy, a branch of study then little understood or cared for in this country. The effort, however, proved to be an abortive one. The novelty of the subject, my own inexperience, and the paucity of students in the city at that season of the year were the causes of my failure. Finding practising and lecturing in so large a city to be up-hill work, I removed to Easton, in this State, whence, after two years and a half spent in earnest work, I went, in 1833, to Cincinnati as demonstrator of anatomy in the Medical College of Ohio. From this institution, after a service of two years, I was called to the chair of pathological anatomy in the Cincinnati College, in which I gave the first regular and systematic course of lectures on that most important branch of anatomy ever delivered in this country. In 1840 I was invited to the chair of surgery in the University of Louisville. In 1850 I became the successor of Dr. Valentine Mott in the University of New York, but returned after the close of the session to the school in Kentucky. In 1856 I accepted the chair of surgery in my alma mater, unanimately tendered me by its honorable Board of Trustees.

"Having been thus actively engaged for so many years as a public teacher, it is not surprising that my pupils should be scattered over the country, while not a few of them are successfully practising in foreign climes. Upwards of fifty thousand diplomas bear my signature. Of the thirty-seven colleagues with whom I have at various times been associated, twenty-six have fallen by the wayside, for the most part ripe in years and full of honor, leaving eleven survivors, among others Willard Parker, Austin Flint, and John W. Draper, of New York; Benjamin Silliman, of New Haven, and our distinguished townsman, Joseph Hancock, five men of whom any profession in any country might justly be proud. It has been said that youth is a blunder, manhood a struggle, and old age a regret. If this be true I have not realized it in my own person; nor need it be true of any one who is true to himself. Struggles of some kind or another are almost the inevitable lot of every man who is not born with a silver spoon in his mouth. I certainly had mine, but they were the struggles of early life, and I thank God for them, for they taught me patience and perseverance and self-reliance, and were powerful aids in developing character. These struggles did not discourage me. On the contrary, I felt as Sheridan did when he made his maiden speech in the British House of Commons—that it was in me and would come out of me; or, as Erskine expressed it on a similar occasion, I felt as if my children were tugging at my coat and urging me on to industry and perseverance that I might supply their necessities. A brave man never yields to despair. His motto is 'Perseverantia omnia vincit.' This has been my motto, and whatever success I may have achieved is due to persistent effort and to a definite aim in life without any faltering or misgiving in regard to the final issue. I have never lost sight of the fact that what a man

soweth he shall reap, or that 'if the spring show no blossoms, autumn will show no fruit.'

"Much has been said about the inspiration of genius. The greatest efforts that have ever been made at the forum, in the pulpit, or in the senate, in ancient or modern times, were the result of hard study and patient labor. Patrick Henry, William Pinckney, Rufus Choate, and others like these, never made a great argument or a great oratorical display without preparation, and the same is true of every profession and every pursuit. After fifty years of earnest work I find myself still in the harness; but although I have reached that age when most men, tired of the cares of life, seek repose in retirement and abandon themselves to the study of religion, the claims of friendship or the contemplation of philosophy, my conviction has always been that it is far better for a man to wear out than to rust out. Brain work, study, and persistent application has been a great comfort to me, as well as a great help; it has enhanced the enjoyment of daily life and added largely to the pleasures of the lecture-room and of authorship; indeed it will always, I am sure, if wisely regulated, be conducive both to health and longevity. A man who abandons himself to a life of inactivity after having always been accustomed to work is, practically, dead.

"In taking a retrospect of my life I have no regrets. I console myself with the belief that I have not lived wholly in vain, and that while much remains undone that might and should have been done, it might be reasonable to suppose that at least some of the seed which I have sown have produced good fruit. It is not given to every man to be a Harvey, a Hunter, a Jenner, a Bichat, a Morton, a Paget or a Virchow. 'By the grace of God,' says St. Paul, 'I am what I am.' No man can rise superior to himself. What is fame? Is it a phantom or is it a reality? Alas! too often the former; too seldom the latter. Few medical works, however meritorious, outlive their authors, and no sooner does a teacher retire from the field of his labor than his pupils worship other gods. Happy, thrice happy, is he who in the evening of his life, as he reviews his past conduct, can say to himself, 'I have been true to my profession. I have been ambitious of its glory; I have done nothing to tarnish its escutcheon.' As I look back through the dark vista of half a century, what memories crowd upon my mind! Kingdoms have crumbled to pieces; new dynasties have sprung up; the world has been drenched in blood by contending armies; millions of human beings have been swept away by pestilence and famine; civilization, commerce, the arts and sciences, religion and education have found new homes; the uttermost parts of the globe have been explored by intrepid navigators and adventurous travellers; time and space have been annihilated by the telegraph, and the employment of steam and the application of machinery have changed the occupations of man and thrown upon us a surplus population, which the wisest statesmen know not how to dispose of. The art and the science of medicine have been completely revolutionized and enriched to an extent which fifty years ago would have baffled the wildest conceptions. During these vast changes, so pregnant in beneficence to mankind, America has not been idle. If she had contributed nothing more to the stock of human happiness than anæsthetics, the world would owe her an everlasting debt of gratitude. The fanciful and mischievous speculations which characterized medicine in the days of my youth have been replaced by sober facts, founded upon more carefully conducted observations and more rational deductions. In preventive

medicine a new field has been opened which, if properly explored and cultivated, as it seems destined to be, will add millions of years to the life of the human race. Oh! for a glance at the profession half a century hence, when man, enlightened and refined by education and redeemed from the thralldom of ignorance and superstition, shall reflect more perfectly than he now does the image of his Maker.

"I thank you, Mr. Chairman, and you, gentlemen, who have honored me with your presence here this evening, for the patience and attention with which you have listened to my rambling remarks. Allow me, before I take my seat, to wish you, one and all, prosperity and happiness, and to drink your health with a heart brimful of gratitude for the many favors that have been showered by my professional brethren upon me."

Professor Rogers delivered the address of welcome to the guests, and Prof. D. W. Yandell replied. The toasts were: "To American Surgery," replied to by Prof. A. C. Post; "The Medical Service of the Army and Navy," by Surgeon Basil Norris; "The Medical Profession," by Dr. Traill Green, and closing remarks were made by Prof. Silliman. * * *

PLEURO-PNEUMONIA IN CATTLE.

DEPARTMENT OF HEALTH, 66 Court Street.

BROOKLYN, April 14, 1879.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Your correspondent, R. W. Finlay, impeaches the State authorities, charged with the extermination of the *bovine lung fever*, with mistaking *simple pleuro-pneumonia* for the specific disease in question. His charge would be a serious one if founded on a substantial basis; but as it is, it is difficult to correctly characterize the statements which he advances in the name of argument. The cattle in the *Blissville distillery stables* were not affected with *contagious pleuro-pneumonia*, because Professor Williams, in opposition to Professors Duguid, McCall, and Walley, pronounced that steers shipped at *Portland, Me.*, were not so affected. If Mr. Finlay has any private information showing that the cattle shipped on the *Ontario* from *Portland, Me.*, were taken from the *Blissville stables*, it will go far to settle the question as to the nature of the disease about which the professors differed at *Liverpool*. If he has not, perhaps he will kindly enlighten your readers as to the possible connection between the cattle shipped at *Portland* and those in the *Blissville stables*.

"Veterinary surgeons and stock-raisers in various parts of the country . . . have failed to discover the innumerable quantity of animals affected, as reported in the daily papers." Mr. Finlay is welcome to his empty honor of demolishing this man of straw, for whom the State authorities are in no sense responsible. This disease exists in a comparatively limited area on the Atlantic seaboard, and its extinction here is a possible and comparatively easy task, while the neglect of it means the gravest injury to the future live stock interests of the country. "At *Blissville* the mortality from the disease was slight. The majority of the animals were slaughtered and sold in the markets as beef. This is not in keeping with a malignant disease theory." If Mr. Finlay and his colleagues had been "well acquainted with the history and pathology of the disease in Europe," they would have known that this is precisely the European record of this disease. In the large cities of Great Britain

and the Continent, it is altogether exceptional for a cow to die of pleuro-pneumonia. The dairymen purchase mainly cows in good condition, and when the first symptoms of the malady are shown, they send them to the slaughter-house for beef. It is a common remark with them that, they would get rich if they could only keep the cows alive for three months after purchase.

But to return to the Blissville stables. Between the time of the first examination by Professors McEachran and Liantard and Mr. Gadsden and the establishing of quarantine, nearly 300 cows had been removed from these stables for slaughter or otherwise, so that comparatively few diseased cattle were left. Yet, of the 600 that remained, we had to send sixty-four to the offal-dock, and about 150 more, slightly affected, went to the Johnson Avenue slaughter-houses. In other words, we slaughtered and furnished indemnity certificates for over one-tenth of the animals left after the diseased had been weeded out, to the best of the owners' knowledge; while, by adding those in which traces of the malady were found, we had a grand total of nearly one-third of the entire stock affected. It will, perhaps, puzzle Mr. Finlay to find another such record in the history of the disease. Mr. F. cannot claim any necessary ignorance of these facts, as this thing was not done in a corner, and every facility was afforded to himself and colleagues for examinations and autopsies on any condemned animals they might select.

It would be easy to multiply cases showing the contagious nature of this affection in and around Brooklyn and New York, but I shall not encroach on your valuable pages further than to mention one or two instances of its conveyance to country districts, where the source of the malady could be undoubtedly traced:

Mr. Wheelock, of Roslyn, L. I., bought two cows from a New York dealer. They sickened soon after, infected the rest of his herd, and six were lost before the plague could be stayed.

Mr. Kenyon was so satisfied it was not contagious, that he purchased and took home two of Mr. W.'s cows. One of these sickened and died, and infected several of his herd, one of which had to be destroyed to prevent the maintenance of the contagion.

Mr. Post, of Westbury, L. I., purchased a cow from a passing herd, said to have come from a swill stable near Brooklyn. She infected his herd and his brother's, and, after heavy losses, they found it needful to kill all the survivors, and begin anew with fresh stock.

Mr. Gilbert Miller, of Katonah, Westchester County, took in a Jersey cow, sent from Mott Haven as a present to his son-in-law. Three months later, his herd was generally infected, and the Jersey cow and two more out of six died.

Mrs. Robertson's herd, occupying a place across the road, suffered from the disease three months later, and five out of twelve died.

Mr. Collins, Fiftieth Street, New York, had a Jersey cow sick with a sporadic (?) disease of the respiratory organs, from which she recovered under the care of a veterinarian. Her calf was sent to the farm of Solomon Mead, of Greenwich, Conn. The calf sickened and died in a little over two weeks after arrival, but infected the whole herd, five of which had died up to the time of my visit.

One of Mr. Mead's cows broke out and went into the herd of Mr. Griffin, and at the time of my visit Mr. G. had lost one and had two sick.

These are examples of what we meet with every day.

If Mr. Finlay can see this disease without tracing similar channels of contagion, I fear that his blindness must be wilful.

I cannot conclude without a reference to Mr. Finlay's sneer at the "stamping out" of the disease. The most superficial acquaintance with the history of this malady would have shown him that this is the only successful method of dealing with this and other fatal contagions of animals. The method was inaugurated in England in the early part of the eighteenth century by advice of Mr. Bates, Surgeon to the Royal Household, for stamping out rinderpest. It was again successfully adopted in the middle of that century to root out a new importation. It was a third time put in force in 1866, and a fourth in 1877, to suppress invasions of the same plague. It was repeatedly resorted to to cut short ovine variola on English soil, and it is now being put in force against the lung fever. On the Continent of Europe it is now recognized as the only economical and effective mode of dealing with rinderpest, and the following countries have successfully resorted to it for the extinction of the bovine lung plague: Switzerland, Mecklenburg, Oldenberg, Schleswig-Holstein, Denmark, Norway and Sweden, and the plague-stricken Holland herself is now putting it in practice. In America it has been repeatedly successful in Massachusetts and Connecticut.

It is doubtless possible to surround the patients and their products with disinfectants, to secure a certain percentage of recoveries, and to let the malady expire by its own self-limitation. But the expense of such a course would far exceed the value of the animals saved, and when attempted on a large scale, over half a dozen different States, it would be subject to incessant lapses and failures, and would thus become a means of spreading the disease. As all sanitarians must admit, that method is the best which will most speedily and effectually extinguish the poison, and do this at the cheapest rate. All of these conditions are met by the *stamping out* process, and whatever retards or hinders this is essentially unsanitary and wasteful. Into this domain no moral question intrudes; it is a purely pecuniary question, and if it could be solved by the slaughter, not of the sick only, but of all the cattle in the infected districts, it would be a much more economical course than to allow the malady to spread till it reaches our open Western ranges, where all attempts at *stamping out* would only repeat the disastrous failures of the steppes and of the unfenced African and Australian pastures.

Yours, &c.,
JAMES LAW.

Obituary.

ISAAC HAYS, M.D.,

OF PHILADELPHIA, PA.

DR. ISAAC HAYS, the editor of the *American Journal of the Medical Sciences*, died late on Saturday, April 12, at his residence, 1525 Locust Street, Philadelphia, after an illness of two months, in the eighty-third year of his age. Dr. Hays was born in Philadelphia, on July 5, 1796. He was educated at the University of Pennsylvania, and graduated from the department of arts in 1816, and from the medical school four years later. He was an office student of the late Nathaniel Chapman, M.D., and a classmate of the late

Dr. George B. Wood. In his profession he was principally famed as an oculist, although his practice was not always limited to this specialty. He began his connection with the *American Journal of the Medical Sciences* in February of the year 1827. He was, therefore, at the time of his death, the oldest living editor in the United States, having been on the staff of the journal for fifty-two years.

When, in 1875, the question was raised as to who was really the oldest living American editor, Henry C. Lea, in an article in the *New York Evening Post*, entitled "Reminiscences and Contemporary Sketches of American Book Publishers," said: "I believe Mr. Bryant has been longer in the editorial chair, but doubt whether Dr. Hays has another senior." William Cullen Bryant's death gave Dr. Hays the undisputed title. The paper of which he was editor was first started in 1820, under the title of the *Philadelphia Journal of Medical and Physical Sciences*, with several eminent physicians—among them Dr. Chapman—as editors. Matthew Carey & Sons were the publishers. Dr. Hays took the place of Dr. Goodman, who resigned to accept the professorship of anatomy in Rutgers Medical College, New York. He immediately became virtually the editor, and at once instituted some important changes, imparting to it a more broadly representative and national character by securing the co-operation of the leading medical minds in all parts of the country, and by the adoption of a new title, the *American Journal of the Medical Sciences*.

In November, 1827, Dr. Hays became sole editor, and so remained until 1869, when his son, Dr. I. Minis Hays, who had graduated from the medical department of the University of Pennsylvania in the previous year, became associated with him. In the year 1843 the success of this journal led to the establishment in connection therewith of a monthly, entitled the *Medical News*, and in 1874 to that of the *Monthly Abstract of Medical Science*, both under the same editorial supervision. Under the name of the *Journal*, when Dr. Hays first took charge of it, were printed the words, "What does the world yet owe to American physicians or surgeons?" This theme was discussed from time to time with much vigor and pointedness in the editorial columns. The ownership of the *Journal* has always remained in the same family, Henry C. Lea, the present publisher, being a grandson of Matthew Carey. It was particularly prosperous toward the close of 1871, and its circulation has been steadily increasing ever since then. Of late years the main duties of editor have fallen upon Dr. I. Minis Hays.

Dr. Hays was a member of the famous Dr. Caspar Wistar party, known as the "Wistar party." Dr. Wistar had been in the habit of giving a social dinner and party at his private residence on every Saturday night. The dinners became a standing thing, and when Dr. Wistar died several of his gentlemen friends formed the aforesaid association. It was composed of twenty gentlemen, and its object was merely social. Among its members were Horace Binney, William Meredith, John Sergeant, Gen. Cadwalader, John K. Kane, Henry C. Carey, Dr. George B. Wood, and Professor Bates.

Dr. Hays edited Hall's edition of "Wilson's American Ornithology," in 8 vols., published in 1828; "Hoblyn's Dictionary of Medical Terms," published in 1846; "Lawrence on Diseases of the Eye," published in 1847; and "Arnott's Elements of Physics," published in 1848.

While editing the *Journal* and all these books, he attended regularly an almost illimitable number of

medical and scientific societies. He was among the founders of more than a dozen associations, the oldest member of a dozen more, the chief officer of another dozen, and the surgeon and attending physician to several hospitals.

He belonged to the American Philosophical Society, was at one time a curator, and for a number of years a member of its council. He was one of the earliest members of the Philadelphia Academy of the Natural Sciences, and from 1865-69 was its president. In the Philadelphia College of Physicians, which he joined in 1835, he was very active and was particularly instrumental in locating it at its present site. There are now but three members of the college living who belonged to it when Dr. Hays came in. When the project of establishing the Franklin Institute of Philadelphia was first discussed, Dr. Hays took a very prominent part in the matter, and when he died, was its oldest member. He was a member of the staff of Mill's Eye Hospital, and was one of the founders of the American Medical Association, having been the author of its code of ethics, adopted in 1869. This code, which inculcated the relations of the medical profession to each other and to the profession at large, has since been adopted by every State and county medical society in the Union.

There were many other societies that claimed Dr. Hays either as a regular or honorary member. He kept in his desk a huge pile of letters mailed to him at various times, informing him of his elections. Letters from societies in Boston, Chicago, Cincinnati, and other large and small cities were among the pile. Though never abroad, he belonged to various European societies, among which were the Royal Society for Northern Antiquities, of Copenhagen; the Medical Society of Hanburg, and the Université D'Ophthalmologie, of Paris. Dr. Hays possessed a very extensive library. The walls of his study were lined with books. Many volumes were of great rarity.

In an editorial notice in the *New York Evening Post*, in 1875, one of Dr. Hays's more recent works, William Cullen Bryant, its then venerable editor, now dead, took occasion to allude complimentarily to Dr. Hays's long editorial labors, comparing them with his own, and substantiating Mr. Lea's statement in expressing the opinion that, next to himself, Dr. Hays was the oldest living editor in continuous service in America.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from April 6 to April 12, 1879.

TOWNS, F. L., Major and Surgeon. Par. 4, S. O. 58, A. G. O., March 11, 1879, directing him to accompany recruits to the Pacific Coast, is revoked, and he will proceed at once to Ft. Vancouver, W. T., and report in person to the Commanding General of Dept. of the Columbia for assignment to duty. S. O. 82, A. G. O., April 5, 1879.

HARTSUFF, A., Major and Surgeon. Assigned to duty as Post Surgeon at Ft. Wayne, Mich., relieving Asst.-Surgeon J. B. Girard. S. O. 55, Dept. of the East, April 10, 1879.

GIRARD, J. B., Capt. and Asst.-Surgeon. Relieved from duty in Dept. of the East, to accompany the 22d Infantry to Dept. of Texas, and, on arrival, report to the Commanding General of that Dept. for assignment to duty. S. O. 83, A. G. O., April 7, 1879.

MERRILL, J. C., 1st Lieut. and Asst. Surgeon. Now

on sick leave, relieved from duty in Dept. of Texas, and to report in person to the Commanding General Dept. of Dakota for assignment to duty. S. O. 87, A. G. O., April 10, 1879.

The following named medical officers, having been found by an Army Retiring Board incapacitated for active service, have been granted leave of absence until further orders, on account of disability, to take effect April 1, 1879: Surgeon, J. H. FRANTZ; Asst.-Surgeons, W. E. WHITEHEAD, T. F. AZPELL, H. J. PHILLIPS, J. W. BUELL. S. O. 81, A. G. O., April 4, 1879.

Medical Items and News.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Comparative statement of cases of Contagious Diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending April 12, 1879.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Apr. 5, 1879..	0	1	164	1	16	31	0	0
Apr. 12, 1879.	0	8	178	1	23	25	3	0

TRICHINOSIS.—Dr. E. J. Bergen, of Martinville, Somerset County, N. J., reports four case of trichinosis in one family. The infected pork was said to have been thoroughly cooked. Death occurred in the father as the result of the disease four weeks after the commencement of the attack.

AMERICAN MEDICAL ASSOCIATION.—The Thirtieth Annual Session will be held in the city of Atlanta, Georgia, commencing on Tuesday, May 6, 1879, at 11 o'clock A.M. The following are the lists of sections, with their officers—Practice of Medicine, *Materia Medica*, and Physiology: Dr. Thos. F. Rochester, Buffalo, N. Y., Chairman; Dr. W. C. Glasgow, St. Louis, Mo., Secretary. Committees appointed to report to this section—On Clinical and Meteorological Records: Dr. N. S. Davis, Illinois, Chairman; Effect of Climate in Colorado on Pulmonary Phthisis: Dr. C. Denison, Col., Chairman. Obstetrics and Diseases of Women and Children: Dr. E. S. Lewis, New Orleans, La., Chairman; ———, Secretary. Surgery and Anatomy: Dr. Moses Gunn, Chicago, Ill., Chairman; Dr. J. R. Weist, Richmond, Ind., Secretary. Medical Jurisprudence, Chemistry, and Psychology: ———, Chairman; Dr. L. M. Eastman, Baltimore, Md., Secretary. State Medicine and Public Hygiene: Dr. John S. Billings, Washington, D. C., Chairman; Dr. J. T. Reeve, Appleton, Wis., Secretary. Ophthalmology, Otology, and Laryngology: Dr. H. Knapp, New York, Chairman; Dr. X. C. Scott, Cleveland, Ohio, Secretary. The following Committees are expected to report—On Prize Essays: Dr. Robert Battey, Rome, Ga., Chairman. On Necrology: Dr. J. M. Toner, Washington, D. C., Chairman. On Catalogue of National Library: Dr. H. C. Wood, Philadelphia, Pa., Chairman. On Recommendations in President Richardson's Address: Dr. T. G. Richardson, New Orleans, La., Chairman. On Ozone: Dr. N. S. Davis, Chicago, Ill., Chairman. On Sanitaria for Consumptives: Dr. H. I. Bowditch, Boston, Mass., Chairman.

On Dr. Seguin's paper on the Intervention of Physicians in Education: Dr. R. J. O'Sullivan, N. Y., Chairman.

REDUCED RATES OF FARE FOR DELEGATES TO THE MEETING OF THE AMERICAN MEDICAL ASSOCIATION.—For the accommodation of delegates, their families and friends, the management of the Kennesaw Route (Western and Atlantic Railroad) have arranged to place on sale, the 4th and 5th of May, tickets to Atlanta, Ga., and return, and good until the 20th of May, as follows: Washington, \$27 75; Alexandria, \$27 50; Charlottesville, \$25 85; Richmond, \$24 65; Norfolk, \$25 00; Petersburg, \$24 65; Lynchburg, \$23 25. The following schedule is in effect: Leave Washington (Va. Midland R. R.), 7 A.M.; Charlottesville (Va. Midland R. R.), 11.55 A.M.; Norfolk (A., M. and O. R. R.), 6.25 A.M.; Richmond (R. and P.), 7.54 A.M.; Petersburg (A., M. and O.), 9.30 A.M.; Lynchburg (A., M. and O.), 2.55 P.M.; Knoxville, 4.14 A.M.; Dalton, 9.06 A.M. Arrive at Atlanta (following day), 12.55 P.M. Pullman sleepers from Washington to Atlanta on this train without change. Delegates will advise Capt. H. L. Peyton, General Agent, 603 Pennsylvania Avenue, Washington, D. C., who will reserve sleeping-car berths.

The New York and Savannah Steamship lines offer members of the Association the special rate of passage from New York to Atlanta, of \$19 50, or excursion tickets at \$32. The route consists of the four new iron steamships "Gate City" (Atlanta), "City of Savannah," "City of Columbus," and "City of Macon," built in 1877-78. The sailing days from New York are Wednesdays and Saturdays, at 3 P.M., arriving at Savannah in 60 hours, and thence, via Central R. R. of Georgia, to Atlanta, the running time between the two cities being about 18 hours over a steel-rail track. Parties leaving here by the "Gate City" (the newest vessel of the fleet), on Wednesday, April 30th, arrive at Savannah Saturday morning, leave by evening train at 7.30, and arrive in Atlanta at noon on Sunday, May 4th, thus allowing a day in which to visit Savannah on the journey, and a day in Atlanta before the meeting of the Association on the 6th. Steamers leaving Boston, Philadelphia, and Baltimore also connect with the C. R. R. at Savannah; but we know of no arrangement having been made with them for special rates. Boston travellers usually come via New York. The rates named above include meals and state-room on steamer. The latter, to insure a choice, should be secured two or three days in advance, from Geo. Yonge, Agent, 409 Broadway.

CREMATION is gaining ground in Europe. The Government of Hamburg has decided to introduce it optionally. It has already been introduced in the same way in Gotha.—*Brit. Med. Journ.*

ANEURISM OF CAROTID AND DISTAL LIGATURE.—An aneurism of the common carotid was cured recently by distal ligation, the relation of parts not permitting ligation between the tumor and the heart. The operation was performed at the Hospital Santo Antonio in Oporto.

QUACKERY TWO CENTURIES AGO!—The following note is copied from the Collections of the Maine Historical Society, Vol. 1, Article on the Early Records of York County (Maine), with original extracts: "—1675, July 6. We present Capt. Francis Rayns for presuming to act the part of a midwife; the delinquent examined by the Court, fined fifty shillings for his offence, and paying the fees, five shillings, is discharged."

Original Communications.

THE ADIRONDACK REGION AS A THERAPEUTICAL AGENT IN THE TREATMENT OF PULMONARY PHTHISIS.

(Read before the Medical Society of the State of New York.)

By ALFRED L. LOOMIS, M.D.,

PROFESSOR OF THE THEORY AND PRACTICE OF MEDICINE IN THE
MEDICAL DEPARTMENT OF NEW YORK UNIVERSITY, N. Y.

PART I.

MR. PRESIDENT AND GENTLEMEN OF THE STATE MEDICAL SOCIETY:—I invite your attention to the Adirondack region as a therapeutical agent in the treatment of pulmonary phthisis. I have long been convinced that the most important factor in the successful management of pulmonary phthisis is to be found in climate. It seems to me that at the present time no subject of medical study is more deserving of attention than the climatic treatment of disease, yet to a student of the medical literature of to-day there is none more confusing and unsatisfactory. Some localities have been considered especially favorable on account of their equability of temperature, others on account of their luxuriant vegetation or their peculiarity of soil; some on account of the dryness, others on account of the humidity of the atmosphere. From the data given, widely differing conclusions have been reached by different observers. In regard to the localities which are claimed to be especially adapted to the treatment of pulmonary phthisis, few writers have carefully observed, for any considerable length of time, the effect of the climate upon individual cases, or, if they have so observed, they have not made public the result of such observations; and on this account very definite conclusions as to the relative merits of the different localities have never been reached.

In the preparation of this paper, my object has been to show the effect of the climate of the Adirondack region upon all the cases of well-developed phthisis, which under my observation have given the region an extended trial. I am largely indebted for facts given, and the history of cases, to my friend Dr. Edward L. Trudeau, who, a phthisical invalid, took up his residence in this region five years ago.

By way of explanation, I would state that clinically and pathologically I recognize three varieties of pulmonary phthisis, viz., catarrhal phthisis, fibrous phthisis, and tubercular phthisis.

In *catarrhal phthisis*, the primary changes are in the cavities of the alveoli and bronchi, and are epithelial and cellular in their nature.

In *fibrous phthisis*, the primary changes occur in the bronchial and alveolar connective-tissue, and are connective-tissue hyperplasias.

In *tubercular phthisis*, the primary changes occur in the lymphoid elements of the lung, associated with connective-tissue hyperplasias forming little masses or nodules, which ordinarily are termed tubercles. The development of tubercle in a lung may be preceded or accompanied by an alveolar cellular process, or by a connective-tissue hyperplasia, and as the one or the other predominates, so is the duration of the case long or short.

In the later stages of these different varieties of phthisis, it is always difficult and sometimes impossible to distinguish the one from the other; but in the

earlier stages, in most cases, the differential diagnosis can readily be made.

The peculiar clinical feature of catarrhal phthisis is, that at the onset the local symptoms are well marked and precede or accompany the constitutional. The local signs may be those of pneumonia or of localized bronchitis of the small tubes, while the peculiar clinical feature of tubercular phthisis is, that at the onset of the disease there are few local signs, while the constitutional disturbance is very marked.

Fibrous phthisis is distinguished from all other forms by its greater chronicity. Usually it commences as a chronic affection, coming on very insidiously. Its chief clinical feature is, that its development is preceded by a chronic bronchitis or pleurisy limited to one lung, or perhaps an unresolved pneumonia. In rare instances, it is developed in the course of some constitutional disease—as syphilis, gout, etc.

These three varieties of pulmonary phthisis not only differ in their origin, mode of development, progress and termination, but necessarily they require different plans of treatment, and are differently affected by climate.

To rightly estimate the effect of the climate of any place or region, it is absolutely necessary that we be able to determine what variety of phthisis it is that is cured or arrested in that locality. Frequently, individuals with catarrhal phthisis will do badly at an altitude at which those with fibrous phthisis will be benefited. Besides, in determining the locality in which phthisical developments will be most likely to be arrested, we must take into account the age and general condition of the individual. For instance, an enfeebled and broken down middle-aged phthisical subject does badly in a high mountain region, but is benefited by the air of the sea.

The region known as the Adirondack region is comprised in that portion of our State which lies north of the Mohawk and west of the Champlain Valley. It may be said to include the counties of Clinton, Franklin, Essex, Hamilton, with portions of adjoining counties, and has an area equal in extent to nearly one-third of the State of New York. Within its limits there is a plateau from 1,500 to 2,000 feet above sea level, 150 miles in length (latitude), and 100 miles in breadth (longitude). On this plateau there are more than two thousand square miles of primitive forests, mostly evergreen, and many hundred lakes and ponds. From the surface of this plateau rise granitic mountain peaks more than five thousand feet in height. The drainage of this table-land is toward Lake Champlain on the east, the St. Lawrence River on the northwest, and the Hudson River on the south. Many of the streams which flow in these different directions intercept each other, and some of them, as well as the lakes, are navigable for light canoes or boats. Occasionally, there are easy portages between these bodies of water, and sometimes we meet with rapids or falls. I doubt whether any region in this country furnishes to the invalid or pleasure-seeker, such a stimulus to out-of-door life.

Mr. Verplanck Colvin, in the conclusion to his report, published in 1874, on the Topographical Survey of the Adirondack Wilderness, uses the following words to express his enthusiasm—words which fitly express the enthusiasm of many another one familiar with this region:

“The Adirondack wilderness may be considered the wonder and glory of New York. It is a vast *natural* park, one immense and silent forest, curiously and beautifully broken by the gleaming waters of a myriad of lakes, between which rugged mountain

ranges rise as a sea of granite billows. At the north-east the mountains culminate within an area of some hundreds of square miles; and here savage, treeless peaks, towering above the timber line, crowd one another, and, standing gloomily shoulder to shoulder rear their rocky crests amid the frosty clouds. The wild beasts may look forth from the ledges on the mountain sides over unbroken woodlands stretching beyond the reach of sight—beyond the blue hazy ridges at the horizon. The voyager by canoe beholds lakes in which these mountains and wild forests are reflected like inverted reality; now wondrous in their dark grandeur and solemnity; now glorious in resplendent autumn color of pearly beauty."

These words are the enthusiastic outburst of one who has a more accurate and comprehensive knowledge of the topography of this region, than has any other man.

It is not surprising that in such a region the tired worker and worn-out invalid find the rest and quiet which is so powerful a restorer of health. Here, as I have already intimated, there is every inducement for one to lead an out-of-door life, the very surroundings infuse new life into the feeble body, and one daily grows stronger and stronger and feels better, scarcely able to tell how or why. One condition which I regard of the greatest importance in seeking a suitable home for a phthisical invalid is here met with, viz.: dryness of soil.

Undoubtedly, a damp warm as well as a damp cold climate acts unfavorably upon phthisical invalids, but the peculiar *dampness* which acts most unfavorably is not usually present in those localities where there is the greatest rain-fall, nor is it present because large bodies of water are in close proximity, but it mainly depends upon the nature of the soil. To avoid this dampness, the soil should be porous and sandy, a loose soil of sufficient porosity to permit the rapid filtering of water from its surface, so that after a heavy rain-fall the surface will soon become dry. All clay soil drains slowly and imperfectly, and the peculiar dampness arises which acts so unfavorably on phthisical invalids. Laennec states, that the dampness arising from such a condition of soil is one of the most certain developing causes of phthisis, and he makes mention of a locality having such a soil, in which the dampness was so constant and of such a character that more than two-thirds of the resident population died of phthisis. In determining the fitness of a locality as a residence for phthisical invalids, I have come to regard the external configuration and conformation of the soil as of greater importance than the amount of rain-fall, or the relative moisture.

The climate of the Adirondack region may be considered a moist, cool climate. The rain-fall is above the average for other portions of the State, and may be roughly estimated at 55 inches. The spring is cool and there is considerable rain until about the middle of June. There is a dry period during the summer, when little rain falls, and the days become hot, while almost without an exception the nights are cool, often cold, and heavy dews fall. There is rarely at any time excessive heat, and during the warmest weather there are but few nights even in August when a blanket is not needed. My friend Dr. Trudeau, who has remained here summer and winter for the past five years, makes the following statement: "That he has never found the mercury above 87° during the past six summers, and this high temperature was only maintained for a few hours during the afternoon. The air during the fall months, with the exception of one or two long rain storms, is bracing and admirably suited to out-of-

door life. During the winter the cold is almost uninterrupted, no thawing of any consequence taking place before the month of March. There is a preponderance of cloudy days and snow storms. The mercury, during January and February, frequently for days at a time stands many degrees below zero. As the cold weather usually continues until the end of March, the thawing takes place quickly, and owing to the sieve-like nature of the soil the snow disappears very rapidly, consequently the change from winter to spring is soon accomplished.

There is no marked preponderance of clear days at any season; on the contrary, the sky, especially in winter, is constantly overcast. This cool, cloudy weather is a marked feature of this climate. The altitude varies with the different localities; but the immense plateau which forms the lake region of the Adirondacks is about 1,800 feet above sea-level. The soil is very light and sandy, with here and there rocks, but little or no clay.

There appears at first sight but little to induce one to consider this locality as favorable for persons affected with phthisis. Hitherto heat and cold and absence of moisture, or an equable temperature, have been regarded as necessary in order to favorable results in the treatment of phthisis; but it has been shown by trial that neither cold, nor heat, nor moisture, alone, are all-sufficient factors in guiding us to a right understanding of the most favorable atmospheric conditions for phthisical patients. In a written communication to me Dr. T— also says: "High mountains, the desert, and the open sea have perhaps given so far the best results in the treatment of chronic chest disease; and yet all these differ widely except in one respect, namely, purity of atmosphere. It is neither hot nor cold air, damp nor dry air, but *pure* air which is necessary to diseased lungs. Many conditions render the atmosphere of these mountains perfectly pure. The elevation of this region, its sandy soil, the undulating nature of the country, which ensures perfect drainage; the absence of cultivation, even of dwellings—all these conditions preclude the presence of telluric or miasmatic poison, and we have a purity of atmosphere unknown in more settled districts. The forests of this region are almost unbroken, stretching over the valleys, covering the mountains often to their very summit, and extending in some directions for nearly a hundred miles, while innumerable lakes dot this elevated plateau, and give moisture to the air. That the atmosphere of such a region, especially when set in motion, should, by its contact with myriads of tree-tops and pine sheaves, become heavily laden with ozone is a natural sequence. Whatever other properties this gas may hereafter be found to possess, we know that it is a powerful disinfectant and Nature's choice agent for counteracting atmospheric impurities. This process, which during the summer months is carried on by all varieties of trees, during the winter months is maintained by the evergreens, while the deciduous trees are deprived of their foliage. Pine, balsam, spruce, and hemlock trees abound, and the air is heavily laden with the resinous odors which they exhale. An agent which it is universally admitted exerts a most beneficial influence on diseased mucous membranes is thus brought in contact with the air-passages, while balsamics, which are also disinfectants, purify the atmosphere, which is constantly impregnated with them. Besides this, the air of the wilderness is optically pure, noticeably free from dust or visible particles of any kind. The invalid, therefore, is here surrounded by a zone of pure air, which separates him, as it were,

from the germ-pervaded world, and his diseased lungs are supplied with a specially vitalized and purified atmosphere, free from germs and impurities of any kind, and laden with the resinous exhalations of myriads of evergreens."

Though as yet but few phthisical invalids have been induced to give the Adirondack region an extended trial, the good results obtained by those who have remained there for any considerable length of time are the strongest arguments in its favor. Dr. T— writes: "My own personal experience and my personal observation of other phthisical invalids lead me to say that any comparison of the relative good effects of the climate of St. Paul, Minn., or of the South, with that of the Adirondack region is decidedly in favor of the latter." In regard to camp life, he writes: "Camping out, which is the peculiar feature of this place, if done in an intelligent manner, from June to October, I consider an important and beneficial measure in the treatment of phthisis; if done carelessly, it is by no means free from risk. The advantages gained by this mode of life are evident. The phthisical invalid for four months, night and day, lives out-of-doors, in a pure atmosphere; he is quiet, has perfect rest, plenty of good food (for which this mode of life gives an amazing relish); he has no opportunity to daily observe the effect upon other phthisical invalids of the disease from which he is suffering; his surroundings are such that he can lie down whenever standing fatigues him, can eat whenever he is hungry, sleep when exhausted, and dress as suits his own comfort—all of which comforts the requirements of society sometimes interfere with.

"All these things—the breathing of the pure air of the wilderness, the perfect rest, the wholesome food, and early hours—combine to make tent-life a powerful weapon in combating this disease.

"Exposure in inclement weather, which this mode of life at times renders almost unavoidable, is well borne in this climate by phthisical invalids who steadily live out of doors. During the past six years I have never seen any evil results from this mode of life; but I have seen men in camp lose their cough and gain in flesh, while it rained daily, and in the midst of occasional frosts and snow-storms."

Dr. Trudeau expresses himself strongly on this point, having faithfully tried tent-life, and he adds: "Many of the risks supposed to attend out-of-door life exist only in the imagination of the timid;" and he believes that tent-life, and a return to the invigorating, out-of-door existence of the savage is Nature's antidote for a disease which is almost an outgrowth of civilization and its enervating influences.

To proceed to results obtained from a fair trial of this region.

CASE I.—Eleven years ago, in the summer of 1867, as an invalid, I first visited this region. For several months previous I had suffered from cough with mucopurulent expectoration, loss of flesh and strength, night-sweats, and other rational and physical signs which attend incipient phthisical development. The only survivor of a family, every member of which (save, perhaps, one) had died of phthisis, I had come to regard my case a critical one. A Southern trip had not relieved it had not aggravated my phthisical symptoms. In this condition I went into this region and into camp, and when, before the summer months had passed, I came out of the Adirondack or north woods, free from cough, with an increase in weight of about twenty pounds, with greater physical vigor than I had known for years, I very naturally became an enthusiast in regard to them.

My personal experience that summer convinced me that there was something in the air of this region especially adapted to diseased lungs; that, if the climate had no direct influence in arresting or preventing phthisical developments, it certainly allayed bronchial irritation, and the phthisical invalid soon became able to spend the greater portion of his time in the open air; still more, his surroundings were such that if a lover of nature or of sport, he necessarily forgot himself, and thus was nature aided, and vigor and health restored.

I would mention here that my personal experience, as well as my experience since that time in regard to its effect upon others, leads me to believe that, during the warm season, a camp or tent life is of the greatest service to pulmonary invalids, if they are not enfeebled.

From time to time, since that summer, eleven years ago, I have sent phthisical invalids into this region. At first I sent them only during the summer months, but I found that while temporary relief was afforded, and in some instances marked improvement took place, in cases of fully developed phthisis the latter was not permanent, and although the winter months might be spent at the South, yet before another summer came around the disease progressed. Not until 1873 was I able to persuade any phthisical invalid to remain during the winter. The effect of the winter climate on this invalid showed so markedly the benefit to be derived from a winter's residence in this region, that from that time, each winter, others have been induced to remain. Fourteen remained last winter.

A brief analysis of the cases which have been under my own personal supervision, or that of Dr. Trudeau, will, I think, enable us to reach some satisfactory conclusions in regard to the therapeutical effects of the climate of the Adirondack region. They are unselected cases, and the only cases of value, as these are the only phthisical invalids who have remained in the region a sufficient length of time to give the climate anything like a fair trial.

CASE II.—Dr. E. L. T., aged twenty-five; family history good; began to lose his health in the winter of 1872. His symptoms very rapidly becoming urgent, he was examined by several physicians. Extensive consolidation at left apex was found, extending posteriorly nearly to angle of scapula; on the right side nothing was discovered save slight pleuritic adhesions at the apex.

He was ordered South, but returned in the spring in no way benefited. On the contrary, night-sweating had set in, and his fever was higher. In the latter part of May he started for the Adirondacks, the ride in the stage being accomplished on an improvised bed. His condition at this time was most unpromising; he had daily fever, night-sweats, profuse and purulent expectoration, had lost his appetite, and was obliged constantly to have recourse to stimulants. Weight about 134 pounds. He began to improve at once, his appetite returned, all his symptoms decreased in severity, and after a stay of more than three months he returned to New York, weighing 146 pounds, with only slight morning cough, presenting the appearance of a man in good health. A few days after his arrival in New York he had a chill, all his old symptoms returned, and he was advised to leave for St. Paul, where he spent the entire winter. He did badly there; was sick the greater portion of the winter. In the spring of 1873 he again went to the Adirondacks. At this time he was in a most debilitated state, was anæmic, emaciated, had daily hectic

fever, constant cough and profuse purulent expectoration.

The marked improvement did not commence at once, as it did the previous summer, and the first of September found him in a wretched condition. I then examined him for the first time, and found complete consolidation of the left lung over the scapula and supra-scapula space, with pleuritic thickenings and adhesions over the infra-clavicular space. On coughing, bronchial râles of large and small size were heard over the consolidated portion of the lung. Over the right infra-clavicular region the respiratory murmur was feeble, and on full inspiration pleuritic friction sounds were heard. I advised him to remain at St. Regis Lake during the winter, and although he was repeatedly warned that such a step would prove fatal, he followed my advice.

From that time he began slowly to improve. Since that time he has lived in this region. At the present time his weight is 158 pounds, a gain of 22 pounds since he first went to the Adirondacks in 1873, and 10 pounds more than was his weight in health. He has slight morning cough and expectoration, his pulse is from 72 to 85, and he presents the appearance of a person in good health. In his lungs evidences still remain of the disease he has so many years combated.

Although he has made three attempts to live in New York, at intervals of two years, each time his removal from the mountains has been followed within ten days by a chill, and a return of pneumonic symptoms—symptoms so ominous that he has become convinced that it will be necessary for him to remain in the Adirondack region for some time to come.

CASE III.—In the fall of 1873, Mr. E., aged twenty, with decided hereditary tendency to phthisis, went into the lake region of the Adirondacks. He had then been ill about 18 months, had spent two winters in Nassau, and for the three months immediately preceding his arrival, he had failed very rapidly. When he first consulted me in September, 1873, I found him extremely emaciated, weighing 108 pounds, pulse habitually ranging from 110 to 130, morning temperature from 102 to 103. He had loss of appetite, night sweats, and a constant harassing cough with slight hemorrhages. Physical examination revealed a large cavity on the right side posteriorly, with entire consolidation of the right lung. At the left apex there was also a small cavity with fine crackling râles over the upper third of the left lung. His condition remained desperate during the following winter, but, in the spring he somewhat recovered his appetite, he regained strength, and he had long intervals during which he was entirely free from fever. He spent the spring and summer of 1874 in camp, and his improvement was very marked. A physical examination of his chest in the fall of 1874 showed a marked decrease in the pulmonary consolidation on the right side, the cavity had apparently diminished in size, and vesicular murmurs could be heard below and on either side of it. On the left side the crackling sounds had disappeared, and no signs of cavity could longer be detected, but broncho-vesicular breathing was still distinctly heard. His heart was hypertrophied, pulse 88, evening temperature 99½, weight 116 pounds. For the succeeding eight months he steadily improved. In June, 1875, after an exposure which it would have been unwise for one in health to risk, he was seized with a prolonged chill, which was very severe and was followed by a pulmonary hemorrhage so profuse that for some time he was thought to be dead, but he lingered until morning, and died from pulmonary congestion and œdema.

Although this case terminated fatally, I regarded it as one of arrested phthisis. The beneficial effects of the climate of this lake region were so positive and well marked in this case, that I assumed the responsibility and induced other phthisical invalids to make a trial of it, contrary to the advice of other physicians, and regardless of the expostulations of friends.

CASE IV.—Mr. M., aged twenty-seven, with a good family history, after an illness of several months, which was marked by cough, expectoration, and loss of flesh, spent the summer of 1870 at Saranac Lake, where he markedly improved, lost his cough, and gained in weight. After his return to New York in the fall, his cough returned, other physical symptoms developed, and he was quite ill throughout the winter. The next summer he returned to the Adirondacks much worse than he was the previous year. Again he improved, and he thought he was almost well. He went to California for the winter, did badly there, and on his return to New York in the spring, two physicians of large experience pronounced his case a hopeless one—one which would probably terminate fatally within six months. In the early summer of 1872 he reached the Adirondacks in a most pitiable condition. Both lungs were extensively diseased. At the apex of the left lung were the physical signs of extensive consolidation and softening. The upper third of the right lung was consolidated, and was the seat of large and small mucous râles. He had hectic fever, extreme dyspnea, a rapid pulse, and other symptoms of advanced phthisis. He soon began to gain flesh and strength, his appetite improved, he coughed less, his expectoration was diminished in quantity, and by early fall he was able to keep out of doors the greater portion of the time. For five years he remained in the lake region. At times his condition was most promising, although little change took place in the physical signs. Last spring, tired of the seclusion, he returned to his home in New York.

Unquestionably this was a case of catarrhal phthisis, and the results obtained from his first summer's residence in the Adirondack region lead me to believe that if Mr. M. had remained in the region the winter succeeding this first summer, he would have reached complete recovery. Even after reaching an advanced stage of the disease, when there was no longer a possibility of recovery, a condition of stasis was reached when he permanently resided in the region.

CASE V.—Mrs. L.—, aged forty, good family history; early in the summer of 1871 went to the Adirondacks. She had been ill eight months with a cough and other phthisical symptoms. At the time of her arrival she was in a state of extreme exhaustion; for several weeks previous she had lived entirely upon beef-tea and champagne. She had a harassing cough, with profuse expectoration and hectic fever. Physical examination revealed a moderate amount of consolidation at the apex of the right lung, with crackling râles of large and small size; no evidence of softening. At once her desire for food returned, and she began to gain flesh and strength; gradually her cough and expectoration diminished, and late in the fall she returned to her home markedly improved. Since that time she has spent some time every summer or fall in this region, and for the last three years none of the rational or physical signs of phthisis have been present.

In this case the rapidity and completeness of the recovery was quite surprising, when we consider how unpromising was the condition of the patient at the time when she first reached the Adirondacks.

CASE VI.—Mr. R.—, aged thirty, with no heredi-

tary tendency to any disease, first consulted me in the spring of 1875. He had been ill six months with cough, expectoration, hectic fever, gradual emaciation, and other well-marked phthisical symptoms. Physical examination of chest revealed consolidation at the apex of the right lung, with sharp crackling râles, most abundant posteriorly, where distinct bronchial breathing could be heard below the spine of the scapula; left lung healthy. I advised him to take up his residence in the Adirondacks. He remained in camp in the lake region during the summer of 1875, with only a slight increase in weight, a slight improvement in strength, and no change in cough or physical signs. During the fall and winter he had several hemorrhages, with fever, and was confined to his bed at different times. Early the next spring he went into camp, and remained until September. When he came out of camp he weighed 181 pounds, had gained forty pounds; he had no cough, no expectoration, no fever. An examination of his chest revealed no abnormal sound, except pleuritic creaking and feeble respiratory murmur posteriorly over the former seat of the pulmonary consolidation. I regarded him a well man, and permitted him to return to his home. He remained well until the following spring, when he had an attack of acute cystitis. He was confined to his bed for six weeks; as soon as he was able to travel he returned to the Adirondacks, but the cystitis became chronic, was complicated by pyelitis and nephritis, and in early winter he died from acute uremia.

At the time Mr. R. took up his residence in the Adirondacks his digestive and assimilating processes were in a feeble condition. Undoubtedly this accounted for the fact that for nearly a year there was little, if any, improvement in his lung disease. His five months' camp life during the second year of his residence in the Adirondacks not only cured his diseased lung, but wrought an entire change in his physical condition. So great was the change that one would scarcely recognize him. When he left the woods the following fall no evidence of lung disease could be detected, nor was any detected during the remainder of his life.

(To be continued.)

DEFORMITY OF THE NOSE,

OCCASIONED BY THE KICK OF A HORSE.—RELIEVED BY A RHINOPLASTIC OPERATION.

By ALFRED C. POST, M.D., LL.D.,

VISITING SURGEON TO THE PRESBYTERIAN HOSPITAL IN THE CITY OF NEW YORK.

(Read before the Medical Society of the State of New York, February 5, 1879.)

EDGAR MARGISON, *et. 18*, admitted to the Presbyterian Hospital June 8, 1878. About ten years ago he received a kick from a horse on the lower part of the nose, fracturing the nasal bones, and displacing the nasal pyramid. The nasal fossæ have been contracted since the injury, so that with the slightest cold he cannot breathe through the nose.

The state of the deformity at the time of his admission is well represented by the accompanying photograph (Fig. 1). The bridge of the nose is depressed, and the apex is turned up so as to expose the anterior nares in a front view.

On the 11th of June I performed the following operation: The patient being etherized, I made a transverse incision through the nasal pyramid, about

three-quarters of an inch above its lower margin. The ends of the incision, as they approached the cheeks, were turned downward along the sulci connecting the alæ nasi with the cheeks. The cartilaginous septum was also divided freely, so as to allow the lower part of the nose to be depressed a little below its normal level. After the divided vessels had been secured, the chasm between the two portions of the

FIG. 1.

nose was measured by a piece of oil-silk, which was reversed upon the forehead, and which served as a pattern for a flap of integument which was dissected from the frontal region, and which was a little larger than the space which it was designed to fill. The flap, which was left adherent by a neck over the nasal bones, was turned on its axis and brought down so as to fill the chasm between the upper and lower portions of the nose, and attached by numerous fine sutures to the margins of the chasm. To prevent the flattening of the new portion of the nose the two sides of the flap were perforated by needles armed with silver wires, and the two ends of the wires were then passed through beads and secured by the method devised by the late Dr. Buck, so as to maintain lateral pressure.

The surface on the forehead, from which the flap had been taken, was dressed with lint saturated with collodion.

13th.—The beads having become imbedded in the integument, the wires were loosened. The flap is in a good condition. There is some conjunctival inflammation. A solution of sulphate of zinc, *gr. ij. to ℥ j.*, was ordered as a collyrium.

16th.—The conjunctival inflammation is subsiding. Removed a portion of the sutures.

17th.—Removed the remaining sutures.

25th.—The union of the flap with the surrounding parts being perfectly consolidated I performed the following operation: The patient being etherized, I divided and unfolded the neck of the flap, and inserted it in a bed which had been made for its reception by the excision of granulations, and of the skin at the margin of the space from which the flap had been taken. The neck of the flap was inserted in a position the reverse of that which it had occupied before the original operation, and secured in that position by sutures. A long pin was passed through the integument at the right side of the wound from which the flap had been taken, passing through the flap at two points, and coming out through the integument

on the left side of the wound; this was secured in the usual way with cotton yarn. The course of the pin was near the upper extremity of the reversed neck of the flap.

30th.—The patient is doing well. The neck of the flap is uniting in its new position.

July 6th.—Since the first of the month, the wound on the forehead has been dressed with adhesive strips every other day, firm pressure being made to keep down the granulations. One of the bead sutures was removed to-day.

8th.—Removed the other bead suture. The wound on the forehead is cicatrizing.

12th.—The patient was allowed to go to his country home, to return next month for further treatment.

August 15th.—Patient was re-admitted to-day. The wound on the forehead is healed. There is a superfluity of skin and subcutaneous tissue at the upper end of the nasal pyramid.

17th.—I performed the following operation: I removed a longitudinal strip of integument, about a quarter of an inch wide, and an inch and a half long. I also dissected out a considerable portion of cellular tissue beneath the neck of the flap to reduce the thickness of the bridge of the nose. And as the apex of the nose was too much depressed on the right side, I removed a wedge-shaped piece of skin from the lower extremity of the transplanted flap on that side. The edges of both wounds were brought together by numerous fine silken sutures.

18th.—No rise of temperature. No inflammation.

20th.—The sutures were removed, and perfect union was found to have taken place. The patient was discharged at his own request.

October 3d.—The patient returned to the hospital, and I performed another operation, which was designed, 1st, to remove an undue fulness of the bridge of the nose, which still remained, in a minor degree, after the last operation; 2d, to elevate the apex of the nose, which was still a little too much depressed.

FIG. 2.

To accomplish these objects I excised an elongated elliptical strip of integument over the bridge of the nose, including the cicatrix which resulted from the last operation, together with an additional portion of subcutaneous tissue. I also made a horizontal incision across the nose, immediately above the line of incision made at the first operation for the separation of the apex from the parts above. Above this incision

a triangular flap was excised on each side, the apices of the triangles looking toward the cheeks, and the bases toward the median line. The base of each triangle was about half an inch in length. The two lateral portions of the nose were approximated by a bead-suture, three-fifths of an inch on either side of the median line. The edges of the vertical and horizontal incisions were brought together by a number of fine silk sutures.

6th.—Some of the sutures were removed to-day.

9th.—The remaining sutures were removed. The wounds have united by the first intention. The form of the nose is nearly perfect. The patient returned to his country home, still wearing the bead-suture.

November 1st.—The patient returned to the city, and I removed the bead-suture. The accompanying photograph was then taken, exhibiting the final result of the series of operations to which he had been subjected, Fig. 2.

REMARKS ON A CASE OF NEURITIS, WITH SECONDARY INFLAMMATION IN THE SPINAL CORD.

By L. PUTZEL, M.D.,

PHYSICIAN TO CLINIC FOR NERVOUS DISEASES, BELLEVUE OUT-DOOR
DEPT., NEW YORK.

I HAVE presented the history of the following case in order to lend additional clinical support to the doctrine of neuritis ascendens—a doctrine which has never rested on a very solid foundation, and which has, of late, been seriously attacked by experimental pathologists. The case is also interesting from a purely clinical standpoint, in order to illustrate the serious results which may follow apparently trifling lesions of the peripheral nerves.

The patient's name is Wm. W., *æt.* thirty-five years; family history unimportant; married, and has healthy children; he has never had syphilis or other venereal disease; his habits have always been good. Patient was in robust health until the war of the rebellion, when he enlisted as a soldier, and contracted dysentery during his term of service. Since his discharge from the army he has had a return of the dysenteric attacks at intervals of a few months. During the early period of my observation, the patient had from three to six watery passages per day.

He first came under my notice at the class for nervous diseases of the Bellevue Out-Door Dept., on Dec. 13, 1877. The patient was anæmic and somewhat emaciated; complained of slight cough and expectoration in the morning; physical exploration of chest not made at that time. A year ago patient received an injury to the right elbow, resulting in the formation of a boil over the olecranon process; this healed kindly in two or three weeks, leaving no apparent traces. About five weeks ago the patient again suffered from a boil, situated in the same locality as the previous one, and coming on without any apparent provocation. The swelling occupied the entire posterior part of the elbow. A month later (nearly two weeks ago), and before the boil had healed, the patient noticed a feeling of numbness appearing on the anterior and posterior surfaces of the forearm. This gradually spread downwards, involving the anterior and posterior aspects of the little finger and the ulnar border of the ring finger; these fingers became parietic, *pari passu* with the anæsthesia. The anæsthetic integument soon began to grow dusky red, became somewhat thickened, and small, whitish scales devel-

oped over its surface. Slight pain and tenderness now appeared in the fold of the elbow and along the course of the ulnar nerve in the forearm. Soon after the patient came under my care, the tenderness spread upward in the arm, along the course of the ulnar nerve into the axillary region, and was even present along the course of the brachial plexus in the neck. Patient was treated by hot douches, actual cautery along the affected nerves, and the descending constant current, as topical remedies; the internal medication consisted of iodide of potassium, fifteen grains three times a day, and thirty drops of the fluid extract of ergot three times a day. In the course of two weeks the pain and tenderness along the nerve trunks had almost entirely disappeared; the skin of the affected region was still insensible to the prick of a pin, but the patient appreciated a less intense faradic current than formerly. The interossei muscles are now becoming paretic; the flexors of the little and ring fingers are apparently somewhat stronger than formerly. Treatment was now restricted to the use of galvanism and the iodide of potassium. The patient remained *in statu quo* until February 10, 1878, when the following notes were taken: general appearance poor; heart sounds normal; signs of incipient phthisis at the apex of right lung; good deal of cough and expectoration; patient suffers from profuse night sweats. Upon examination of the arm, attention is attracted by the dusky redness of the skin in regions which accurately represent the distribution of the internal and external cutaneous nerves and the cutaneous branch of the musculo-spiral. The patient is unable to feel the prick of a pin even when it draws blood; does not feel constant current of thirty-two Stoecher's cells; feels quite readily a secondary faradic current of moderate intensity. No tenderness on pressure along any of nerve trunks. Right hand forces dynamometer to 46, left hand to 180°. On inspection, it is found that the adductor pollicis can barely adduct the thumb, and the dorsal interossei are considerably atrophied. On asking the patient to move his fingers, it is found that the palmar interossei and the three inner lumbricales do not act as vigorously as in the left hand, and it is reasonable to suppose that they are atrophied. The motor nerve affected in the forearm is, therefore, the ulnar. In the arm, the ulnar nerve can be traced from the groove between the internal condyle and the olecranon process upward into the axilla as a thick, indurated cord, but is not, however, sensitive to pressure at the present time; the tenderness along the brachial plexus has also disappeared. A red patch is visible on the side of the neck and the tip of ear. This region, corresponding to the auricularis magnus nerve, feels numb, and on testing it with the æsthesiometer, it is evidently markedly anæsthetic. The two points of the æsthesiometer are only distinguished apart at thirty mm., and on the corresponding portion of the left side at fifteen mm. Immediately below the inferior angle of the right scapula is a spot nearly as large as a silver dollar, at which the skin presents the same appearances as in the neck and arm; this region is also anæsthetic, and two points cannot be distinguished apart over this spot. To-day the patient informs me, for the first time, of his dysenteric affection. Ordered subnitrate of bismuth, gr. xxx., t. i. d., which, in a few days, reduced the number of passages to two or three per diem, and rendered them healthy in appearance; atropia was ordered for the night sweats, with excellent results. The iodide of potassium was continued in the same doses as before, and the constant descending current was passed down the cervical spine, and along the course of the brachial plexus

and of the nerves of the arm and forearm, every other day.

April 2, 1878, general health greatly improved; coughs very little; no night sweats; has one to two healthy passages from the bowels daily. The patient is now able to adduct the thumb to the base of the ring finger, and can abduct and adduct all the fingers except the ring finger. The eruption on the forearm has faded a great deal, especially toward its centre. Sensation has improved very little; pain is absent, except in the little finger and the ulnar side of the ring finger (hot, smarting pain). The anæsthesia of the reddened patch on the side of the neck is, perhaps, a little less marked than at the date of the last note, and the eruption is somewhat paler. The patient informs me to-day that he has noticed, since the beginning of the week, a numb, red spot on the middle of the thigh anteriorly, and about six inches below Poupert's ligament. This patch of eruption, which is as large as a silver dollar, and paler in the centre than at the periphery, is markedly anæsthetic. A similar spot, as large as a silver dime, is found over the left deltoid. The sexual appetite, which had been diminished, is now improving. The patient continued to improve very slowly until the winter of 1878, when he returned to work as a night watchman, and passed out of my observation.

This case has important bearings upon the question of neuritis ascendens and neuritis migrans. During the last twenty-five years there has been a strong tendency among neurologists to entirely discard the old doctrine of reflex paralyses; but there is no doubt that in a few cases the theory of reflex inhibitory action is alone sufficient to account for the paralysis produced. Thus, Landry reports a case of paralysis, associated with anteversion of the uterus, which disappeared immediately after the organ was replaced in its proper position. M. Rosenthal observed the disappearance of a suddenly developed paraparesis after the extraction of a needle which had been introduced into the vagina. Madge reports a case of paralysis developing during pregnancy which disappeared after the delivery of a dead fœtus of four months.

These observations correspond with the experiments of Lewisson, who produced paraplegia in animals by compression of the kidneys.

But this theory will evidently not suffice to explain all cases of this nature. In many instances post-mortem examination revealed the presence of inflammatory processes in the spinal cord or its meninges, in cases which had been regarded during life as examples of reflex paralysis from bladder or uterine disease, etc. The older cases of this character were deficient in microscopical examination of the medullary tissue, and must therefore be discarded. In order to explain the cases included in this category in which anatomical lesions were found in the spinal cord, resort was had to the theory of neuritis migrans, and this doctrine has been favorably entertained by the majority of living pathologists. In addition to the clinical aspects of the question, physiological experiments were also adduced to substantiate it. Thus, Tiesler, Klemm, Feinberg, and Niedick made numerous experiments upon animals by producing irritation of the sciatic nerve in some portion of its course, either by injecting a foreign matter into its substance, or by cauterizing it with nitrate of silver or caustic potassa. With the exception of Feinberg, these observers announced as the results of their investigations that the irritation of the nerve in the manner referred to produces neuritis at the irritated spot, and that, furthermore, evidences of inflammation ap-

pear in the course of the nerves, although the nerve-tissue may be perfectly healthy between two inflammatory foci. In addition, scattered foyers of myelitis were found disseminated throughout the cord. None of these experimenters, however, resorted to microscopical examination of the tissues, nor did they compare the appearances presented with those found in healthy animals. Feinberg found, as the result of his investigations, that neuritis was produced at that portion of the nerve which had been irritated, but that the more central parts of the nerve were intact. He, nevertheless, obtained evidences of myelitis in the cord. Feinberg is inclined to regard this myelitic process as produced by reflex irritation of vaso-motor nerves (contraction and secondary dilatation of the medullary vessels).

In December, 1877, Ottomar Rosenbach published an article in *Kleb's Archiv f. exp. Path. u. Pharmak.*, in which he arrived at entirely opposite results from those of the observers previously mentioned. Dr. Rosenbach made a series of very careful experiments upon the sciatic and pneumogastric nerves in rabbits, and, although he could develop a perineuritis of the nerve at the irritated point, in not a single instance was he able to discover any evidences of neuritis migrans or of consecutive myelitis. All his experiments were accompanied by careful microscopical examinations—a precaution which had been omitted in the above-mentioned researches. Rosenbach also calls attention to the fact that no controlling observations were made upon healthy animals by either Klemm, Tiesler, Feinberg, or Niedick, and that many of the appearances which the latter regarded as pathological were, in fact, perfectly normal.

Whether or not these experiments of Rosenbach disprove the production of neuritis migrans in rabbits, we shall not discuss now. We are, however, justified in the assertion that its existence has not been experimentally established, and that other and more careful experiments are necessary to settle this vexed question.

We must therefore rely for a solution of the problem upon pathological and clinical data.

Kussmaul reported a case in which he observed atheromatous degeneration of the arteries in the pelvis, with partial fatty degeneration of both sciatic nerves.

Leyden reports two cases in his *Kl. f. Rueckenmarksk.*, in both of which the paralyzes were secondary to disease of the bladder, and in which the autopsy showed the existence of widespread myelitic softening. The myelitis started from that part of the cord in which the nerves supplying the bladder originate, and we are therefore naturally led to suppose that the inflammatory process passed upward from the bladder, and along the nerves, until it reached the cord. But Leyden himself remarks that there is no positive proof in support of this hypothesis. I have been unable to discover any other analogous cases of equal importance in a somewhat cursory survey of the medical literature which has appeared since the publication of Leyden's work.

The case which forms the subject of this paper appears to me to fill an hiatus in this direction. The primary affection was evidently a neuritis of the internal cutaneous, external cutaneous, and ulnar nerves, caused by an extension of inflammation from the boil situated on the elbow. The fact that the boil was primarily seated over the olecranon process, and from thence spread internally and externally, is a sufficient anatomical explanation of the fact that the three nerves in question were implicated to the exclusion

of the other nerves situated in the fold of the elbow. At a later period pain and tenderness became evident along the course of the ulnar nerve in the arm, and the nerve could be traced as a thickened, indurated cord from the back of the inner condyle, along the inner side of the arm, into the axillary space. These phenomena undoubtedly indicated extension of the inflammation along the ulnar nerve. At a still later period tenderness became evident along the course of the brachial plexus in the neck, indicating the further extension of the neuritis along the nerve-trunk. The next nerve to become involved was the auricularis magnus, as was evidenced by the appearance of anaesthesia and of the trophic eruption, referred to previously, in its distribution to the lobe of the ear and to the side of the neck. Now, the ulnar nerve which had been previously implicated arises from the 8th cervical and 1st dorsal nerves, while the auricularis magnus arises from the 2d or 3d cervical nerve. If we acknowledge that the implication of the auricularis magnus was secondary to that of the ulnar nerve (and no other explanation is open to us), we are forced to conclude that the affection of the former nerve was caused by some inflammatory process in the spinal cord. This idea is still further strengthened by the subsequent appearance of similar spots of anaesthesia and eruption in other portions of the body (deltoid, scapula, thigh). What the nature of this medullary lesion was we are unable to state. It may have been a disseminated chronic myelitis, or the inflammation may have been limited to the meninges. The spinal symptoms were so slight, that it would be rash to venture a differential diagnosis between these two conditions.

In conclusion, it appears to us that this case demonstrates, from a clinical standpoint (and with almost as much positiveness as a successful physiological experiment), that ascending neuritis is capable of developing secondary inflammatory changes in the cord, by means of a simple extension of the neuritic process *per continuitatem*.

252 E. 48TH ST.

OSTEOTOMY FOR THE CORRECTION OF RACHITIC DEFORMITIES OF THE LEGS.

By CHARLES T. POORE, M.D.,

SURGEON TO ST. MARY'S FREE HOSPITAL FOR CHILDREN, AND TO CHARITY HOSPITAL, NEW YORK.

In the *MEDICAL RECORD* for September 7, 1878, I published three cases of osteotomy for the correction of rachitic deformities. The three following cases are in illustration of the same operation.

CASE IV.—Henry H., aged five years, was admitted into St. Mary's Hospital Oct. 1, 1878. He had enlarged epiphyses at the wrist, and excurvation of both tibiae.

Oct. 5.—Patient was etherized and osteotomy was done on both limbs. The fibula was divided first, and then the tibia; counter-openings were made on the inner aspect of the legs, and carbolized horsehair passed. The limbs were put up in a straight position.

Oct. 6.—Dressings removed. There was no swelling or redness about the wound. Horsehair removed and new dressings applied.

Oct. 14.—Dressing removed; wounds all closed; limbs put up in plaster-of-Paris. The temperature since the operation has not been above 99°.

Nov. 7.—Plaster-of-Paris removed; limbs straight. Feb. 8, 1879.—Patient discharged.

CASE V.—John C., aged two and a half years, was admitted into St. Mary's Hospital Oct. 4, 1878. He has enlarged epiphysis and bow-legs to a marked degree.

Oct. 12.—Osteotomy was done on both legs in the same manner as in case No. IV. The bones were *very hard* and section was made slowly on this account. Counter-openings made and horsehair passed through. Limbs put up in a straight position. Sol. morph., sulph. mag., ℥ iv.

Oct. 13.—Dressings removed. Horsehair taken out; new dressings applied.

Oct. 21.—On removing the dressings to-day the wounds in the right leg were all closed, and the limb was put up in plaster-of-Paris. There was some suppuration from the tibial wound of the left leg. Dressings reapplied.

Oct. 24.—Left leg put up in plaster-of-Paris.

Nov. 7.—All splint removed; union firm; limbs straight. Patient was kept in the hospital until he could walk well, and was discharged cured Dec. 10th.

CASE VI.—Thomas C., three years of age, was admitted into St. Mary's Hospital Oct. 24, 1878, suffering from bow-legs. He shows the results of rickets in various parts of his body. Figure 1 is from a photograph taken at the time of admission.

FIG. 1.

Nov. 11.—Patient etherized, and osteotomy done on both legs, the fibula being first divided and then the tibia. There was considerable hemorrhage from left leg; counter-openings made and horsehair passed through; limbs put up in a straight position.

There was some slight suppuration from both legs. They were put up in plaster-of-Paris on the 16th. On the 29th, as the limbs were not as straight as they should be on account of the plaster splint getting loose, the tibiae were forcibly straightened and the plaster reapplied.

Dec. 23.—All splints removed and patient allowed to go about.

Jan. 3.—Patient was discharged. Figure 2 was taken just before he went home.

It is worthy of notice that in case No. IV. the bones were *very hard*, more so than in any of the cases that I have operated upon, although it was the youngest patient, and is an illustration of the fact that the bones in some cases may become sclerosed at

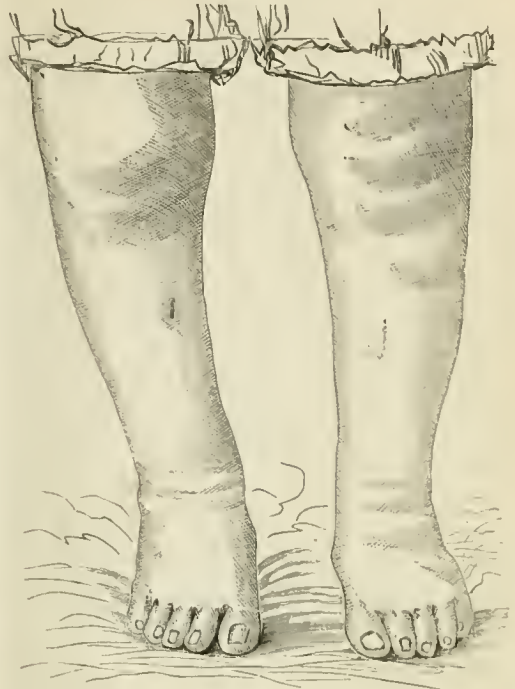

FIG. 2.

a comparatively early age. I do not think that mechanical appliance could have had any influence in straightening these limbs. I have lately seen one of the patients operated upon in May last. He walks well, without any awkward gait, and there has been no change in the legs.

In cases IV. and V., there was, during the latter part of the second and the beginning of the third week, an elevation of temperature which I cannot account for. I do not think that it had any thing to do with the operation, as the wounds all did well. The suppuration in case V. was too slight to have been an element in its causation.

Those cases where the curve is acute and near the ankle are more difficult to correct than where the curvature is long, and although the great toe may be on a line with the inner border of the patella, yet there is apt to remain a bend, due in some cases, I think, to the enlargement of the inner malleolus.

It should be added that all these operations were done, and the wounds treated antiseptically. Section in all these cases was made with a chisel.

“ALOEOPOTHY.”—The following was received by a medical director of a life insurance company from an Eclectic in Missouri:

“Dear Sir, in reply to within I will state that I am the only physician in this town. I presume that I am not what you term ‘Regular School’ as I am a graduate of the Eclectic School and not an ‘Aloepoth.’ There are only two other graduates in the county, and they are Eclectics. The ‘Regulars’ or Aloepoths have played out in this country!”

INCONTINENCE OF URINE OF EIGHT YEARS' DURATION RELIEVED BY CIRCUMCISION.

By C. E. NICHOLS, M.D.,

PHYSICIAN TO TROY HOSPITAL, N. Y.

The following case illustrates the prompt relief that can often be afforded in cases of reflex disorders by removing the peripheral source of irritation, even though the duration be sufficient to lead us to expect some continuation from *habit*.

M. L., male, æt. 15 years, had suffered from incontinence of urine for eight years. During that period he had not voided his urine once in a normal manner, but was subjected to a constant urinous dribbling from the penis day and night. At times he suffered severely from pain in the penis and hypogastric region, which was attributed to some vesical disorder. In the autumn of 1877 he entered Troy Hospital as a surgical patient, but left after remaining a few weeks, having been subjected to no treatment.

He was readmitted in October, 1878, and was repeatedly examined for stone in the bladder or other vesical disease, but with negative results.

My attention was called to him in February, 1879, during which month I was on service at the hospital, and I was requested to examine him with a view to the relief of his distressing condition. From the constant stilticidium of the urine his clothes were wet and offensive, no measures having been found practical to collect the urine in a suitable reservoir. He was still subject to frequent and very severe paroxysms of pain in the penis and hypogastric region, and, taken all in all, he was a disgusting and pitiable object. I found that he possessed an unusually long and somewhat thickened prepuce; that the orifice was small, and the glans penis, as felt through the foreskin, was exceedingly sensitive. The pain and nervous excitement resulting from the gentle manipulation of the glans penis during my examination led me to conclude that the probable cause of the trouble lay in the phimosis. To complete the diagnosis, however, I placed him under the influence of chloroform, and having satisfied myself that no condition existed in the pelvic organs to which the symptoms could be properly attributed, I availed myself of the condition of insensibility, and performed circumcision, removing a liberal portion of the prepuce.

The effect was very marked, and though the exposure of the inflamed and exceedingly sensitive glans was a source of suffering, yet immediately after the operation he was able to retain his urine for a period of two to three hours for the first time in eight years. The bladder rapidly improved in tolerance, and he progressed favorably in every way; but, owing to disorderly conduct and his indifference to cleanliness, which resulted from his eight years' experience, he was discharged from the hospital March 18th.

He called on me a day or two previous to the writing of this (April 9, 1879), and reported himself as free from any trouble or inconvenience in connection with the urinary organs, while at the same time he had acquired a proper sense of his duty in regard to the cleanly care of his person.

“THE DOCTOR WOMAN,” by AIKEN HEART, M.D.—This is a clever little poem founded on the electrifying sensations experienced during direct auscultation by a lovely medical woman. The book is neatly printed and appropriately illustrated.

Reports of Hospitals.

BELLEVUE HOSPITAL.

REPORTS OF PRACTICE AND PECULIARITIES OF TREATMENT.

LEAD-COLIC—CROTON OIL AND OPIUM.

A male patient, a worker in a paint manufactory, suffered from pain about the umbilicus, the usual region for the pain of lead-colic, and had a well-marked blue line along the edge of the gums. The prescription was the following: Croton oil in half-drop doses, combined with opium sufficient to relieve the pain, and repeated every three or four hours until free evacuation of the bowels was produced.

PULMONARY EMPHYSEMA—AUTUMNAL ATTACKS OF SPASMODIC ASTHMA.

A female patient, forty-eight years of age, and the mother of seventeen children, suffered from autumnal attacks of spasmodic asthma. She stated that when the cold weather appeared she recovered without the aid of medicine. Associated with it were the physical signs of emphysema. The attacks of coughing were accompanied by a pearly pellet-like expectoration. One interesting feature in the case was the absence of hereditary history. For this class of cases, in addition to a general tonic plan of treatment, the following was recommended:

B. Potass iodid. ʒij.
Hoffman's anodyne. ʒss.
Syr. prun. Virginiana. ʒiv.
M. et S. teaspoonful four times a day*

CHOREA.

The case was interesting because of the degree of the disease and the age of the patient.

A male patient, æt. forty-eight years, and a carpenter by trade, suffered from chills and fever for one year. At the end of that time, four years ago, he began to have choreic movements in the lower extremities, which caused him to walk like a drunken man. Not long after, the entire body was affected, and the movements had continued without interruption up to the time he was admitted to the hospital.

When admitted to the hospital his jerkings were so severe that it was necessary to confine him to the bed by means of straps.

His intellect was clear, but his power of expression was very much disturbed.

He was receiving gr. lx. of bromide of potassium, night and morning, and while taking the remedy the severity of the movements was considerably reduced.

ACUTE ARTICULAR RHEUMATISM—EXCEPTION WITH REFERENCE TO THE TIME OF THE OCCURRENCE OF THE PRIMARY ATTACK.

A male patient, æt. fifty years, was suffering from his second attack of acute articular rheumatism. The first attack occurred when he was forty-seven years of age, and in that particular the case was chiefly interesting, primary attacks of the disease being very unfrequent after the age of forty has been reached. His symptoms yielded quite promptly to the use of table-spoonful doses of a saturated solution of bicarbonate of soda, with twenty grains of salicylic acid, every three hours.

SPINAL ABSCESS—TREATMENT BY INJECTIONS OF CARBOLIC ACID.

A male patient, æt. twenty six, had upon the upper portion of the thigh a large abscess, which was supposed to have its origin in caries of some of the lumbar vertebrae.

The points of interest in the case were that it was a spinal abscess, which originated in the lumbar region, and terminated in two long sinuous tracts, one extending down upon the right side, passing under Poupart's ligament, and then spreading out and forming a large abscess, which had opened in the femoral region; the other running down upon the left side, and opening over the anterior superior spinous process of the ilium.

The plan of treatment proposed was—*first*, to establish an opening near the point at which the pus emerged from beneath Poupart's ligament; *second*, to empty the abscess upon the thigh below, wash its cavity thoroughly with carbolized water, and bring its walls in contact by means of a bandage; *third*, to introduce a soft catheter, carrying it up until the bodies of the vertebrae were reached, cleansing the entire surface of the sinuous tract by injections of carbolized water, and bringing the disinfectant solution in contact with the carious bone. The surgeon did not expect to prevent air from entering the wound and the sinus, but the operation was done under Lister's method, for the purpose of disinfecting the air which might enter.

PNEUMONIA AT THE APEX—THREE CASES—SPONTANEOUS RECOVERY IN TWO CASES.

Three cases of pneumonia which were interesting for study were seen.

CASE I.—Pneumonic Fever, pursuing a short course, and ending by crisis without active interference in the way of treatment.—Its history was as follows: A male patient, æt. 17, a farm laborer, was admitted to the hospital, January 10, 1879. Family history negative, and habits good. During the last two months he had had cough with moderate amount of expectoration. On the evening of January 9th, he began to feel unwell, and had a chill. During the week previous to the chill the patient was in his usual health. On the following morning he had moderate pain in the right side, increased by respiratory movement. Headache and vomiting were absent, and there was no marked debility. There were no positive signs of consolidation at the time of admission, but the respiratory movement was nearly suppressed over the lower lobes, as the result of the pain. The face was flushed and the tongue coated with a heavy white fur. The urine was acid, had a specific gravity of 1024, and did not contain albumen. The pulse was 126, the respiration 36, and the temperature in the morning, 103 $\frac{1}{4}$ ° F.; in the evening, 103 $\frac{1}{4}$ ° F.

Jan. 11.—Morning: pulse 120; respiration 30; temperature 103 $\frac{1}{4}$ ° F. Noon: pulse 120; respiration 36; temperature 104 $\frac{1}{2}$ ° F. 5 P.M.: pulse 96; respiration 40; and at 6.30 P.M. the temperature was 104 $\frac{1}{2}$ ° F. At that time indistinct bronchial respiration was detected at the apex of the right lung. The patient received four pints of milk and two eggs in twenty-four hours. No medicinal treatment.

Jan. 12.—Morning temperature was 104 $\frac{1}{2}$ ° F. At 1 P.M. the temperature was 105° F., and at 6 P.M. it was the same. The physical signs remained unchanged. There was no characteristic pneumonic sputa.

Jan. 13.—At 5 A.M. the pulse was 120; the respiration 32; and the temperature 103 $\frac{1}{2}$ ° F. At 1 P.M.

the temperature was 104° F. At 5 P.M. the pulse was 100; the respiration 40; and at 6 P.M. the temperature was 103° F. The physical signs remained the same.

Jan. 14.—Morning: the pulse was 100; the respiration 50; and the temperature 103 $\frac{1}{4}$ ° F. At 1 P.M. the temperature was 104° F.; at 5 P.M. the pulse was 100; the respiration 54; and at 6 P.M. the temperature was 104° F. Bronchial breathing at the apex of the right lung. Sputa copious, transparent, and viscid. No medicinal treatment.

Jan. 15.—Seventh day from the chill. Morning: pulse 62; respiration 24; and temperature 99° F. At 6 P.M. the pulse was 64; the respiration 28; and the temperature 99 $\frac{1}{2}$ ° F. The physical signs remained unchanged, notwithstanding the marked change in the general condition of the patient, and the case was regarded as a typical illustration of the view that this disease is not a local disease, but a fever with pneumonic manifestations.

Jan. 16.—Morning: the pulse was 66; the respiration 34; and the temperature 98 $\frac{1}{4}$ ° F. At 6 P.M. the pulse was 52; the respiration 36; and the temperature 98 $\frac{1}{2}$ ° F. The case then illustrated the fact that sometimes the pulse falls below the average at the time of convalescence from pneumonia. On physical examination there was found a slight crepitan râle (redux) over the affected portion of the lung; the entire lobe was not solidified.

CASE II.—Pneumonia at the apex of right lung.—Treatment.—Recovery.

A female patient, æt. 40, was admitted to the hospital on January 6, 1879. Family history unimportant. Had always enjoyed good health, and had not had any pulmonary affection until the present.

On January 2d, at about 3 P.M., she was suddenly seized with a chill, and at the same time vomited. A few hours later she had pain in the right side, most intense near the nipple, and extending towards the shoulder.

On January 3d, she had epistaxis, which appeared to be caused by violent coughing. The sputa was small in quantity, viscid and uncolored. Pain in various parts of the body.

On the day of admission she was suffering from headache, anorexia, troublesome cough, and some diarrhœa. Pulse 120; respiration 40; temperature 104 $\frac{1}{4}$ ° F., and face flushed. Characteristic rusty-colored expectoration was present, and there were signs of solidification over the upper lobe of the right lung. The urine was acid, had a specific gravity of 1018, a slight trace of albumen, and an abundance of large granular casts.

Jan. 8.—Morning: pulse 124; respiration 38; and temperature 104° F. At 1 P.M. the pulse was 114; the respiration 35; and the temperature 104° F.

She then received small doses of morphia (U. S. solution) to relieve the pain in the side, and also small doses of sweet spirits of nitre.

Jan. 9.—Bronchial breathing and bronchophony over the upper lobe of the right lung.

In the morning the pulse was 110; the respiration 34; and the temperature 103 $\frac{1}{4}$ ° F. In the evening the pulse was 110; the respiration 32; and the temperature 102° F.

Jan. 10.—Morning: pulse 102; respiration 29; and temperature 100 $\frac{1}{4}$ ° F.

Evening: pulse 104; respiration 32; and temperature 100 $\frac{1}{4}$ ° F.

The patient was receiving milk and whiskey in half-ounce doses, every three hours. Twenty minims of the tincture of digitalis were added to the morphia, and the spirits of nitre was continued.

Jan. 11.—Morning: pulse 56; respiration 30; and temperature $99\frac{1}{2}^{\circ}$ F.

Evening: pulse 57; respiration 30; and temperature 100° F.

Jan. 12.—Morning: pulse 55; respiration 29; and temperature 99° F.

Evening: temperature 99° F.

From that date there was no history of fever, and resolution was indicated by the presence of crepitant and subcrepitant râles (reduced) and a change of the bronchial into the broncho-vesicular respiration.

The disease was of short duration. The patient was taken with a chill on Jan. 2d, and on the eighth day of the disease (Jan. 10th) there was a marked decline in all the symptoms.

It was left for the observers to decide, each for himself, whether the disease was brought to its happy termination by the remedies administered, or whether recovery was due to the effort of Nature.

CASE III.—*Pneumonia at the apex—Treatment, active and antipyretic—Case progressing favorably.*

The general condition of this patient was not good, and was such as to render him less able to tolerate the affection.

A male patient, colored, and aged 48, was admitted to the hospital on the 6th of January, 1879. Family history negative. He had led a wandering life, but had had no serious illness, except intermittent fever several years ago.

On Jan. 3d the patient arose feeling as well as usual, but in the middle of the forenoon was seized with a severe chill. He was unable to continue his work, returned home, went to bed, and soon began to suffer from pain in the head, back, and limbs. In the evening he had a sharp pain in the right side near the nipple. He had some cough; expectorated a thin white viscid sputa. The cough was suppressed as much as possible, on account of the pain produced by it. He suffered from dyspnoea, anorexia, and slight diarrhoea, and when admitted had headache and a temperature at 12.30 P.M. of $104\frac{1}{2}^{\circ}$ F. At 4.15 P.M. his temperature was $105\frac{1}{4}^{\circ}$ F. and he received xxv. grs. of the sulphate of quinine.

At 7.15 the temperature was 103° F. At that hour of the day, fall in temperature would not be expected in the natural progress of the disease, and it was altogether probable, therefore, that the decline was due to the large dose of quinine. There were bronchial breathing and bronchophony over the upper lobe of the right lung, most marked behind. There were no râles present. The urine was acid, had a specific gravity of 1020, did not contain albumen, but contained oxalate of lime and some pus and blood. There were also present epithelial and granular casts. The patient had urethral stricture.

On Jan. 8th the pulse in the morning was 120; the respiration 40; and the temperature $104\frac{1}{2}^{\circ}$ F.

At 12.30 P.M. the temperature was $105\frac{1}{2}^{\circ}$ F., and xl. grs. of the sulphate of quinine with xix. ℥ of aromatic sulphuric acid and xx. ℥ of tincture of opium were given by enema.

At 7.10 P.M. the temperature was 104° F. A few crepitant râles were heard over the upper lobe of the right lung in front.

Sweet spirits of nitre was also administered in this case.

Jan. 9.—Morning: pulse 96; respiration 30; and temperature 102° F.

At 12.30 P.M. the temperature was $105\frac{1}{2}^{\circ}$ F.; and at 7.10, $105\frac{1}{2}^{\circ}$ F. At 8 P.M. he received xx. grs. of quinine.

Jan. 10.—Morning: pulse 84; respiration 30; and temperature $100\frac{1}{2}^{\circ}$ F.

At 12.30 P.M. the temperature was $101\frac{1}{2}^{\circ}$ F., and at 7.20 P.M. $105\frac{3}{8}^{\circ}$ F.

Subcrepitant râles could be heard over a circumscribed space over the upper lobe of the right lung behind. The patient received milk and eggs, and whiskey in half-ounce doses every three hours.

Jan. 11.—Morning: pulse 90; respiration 28; and temperature $102\frac{3}{4}^{\circ}$ F.

At 1 P.M. the temperature was $101\frac{1}{2}^{\circ}$ F., and at 7 P.M. $104\frac{1}{8}^{\circ}$ F.

The patient had a moderate diarrhoea which was checked by chalk and opium powders.

Jan. 12.—The morning temperature was $101\frac{1}{2}^{\circ}$ F., and at 7 P.M. it was $103\frac{1}{2}^{\circ}$ F.

The case was progressing very satisfactorily, although the lung had not yet completely resolved. To meet such symptoms as might arise and to nourish the patient well were the indications.

Progress of Medical Science.

SATURNINE HEMIPLEGIA.—At a recent meeting of the *Société Médicale des Hôpitaux*, in Paris, M. Debore reported a remarkable case of this rare affection, of which only five or six cases have hitherto been reported. The patient was a worker in lead, and when brought to the hospital was suffering from coma and delirium. He gradually regained consciousness, but remained hemiplegic on the left side. Four months later the hemiplegia still persisted, but the patient could walk, dragging the left leg slightly. The mouth was drawn to the other side: no ptosis; anaesthesia of the left side of the tongue; impairment of hearing on the left side, with obstruction of the Eustachian tube; central scotoma on the left side, but vision perfect on the right side. In the hope of curing the hemi-anaesthesia, M. Debore applied the electro-magnet of Faraday, and in half an hour he demonstrated an incomplete return of sensibility, with improvement of the sight and hearing, but not of the senses of taste and smell. M. Debore thinks that in this case he has excluded by careful examination the possibility of simulation. Experiments with a false magnet remained negative, while those with a true electro-magnet gave the above results.—*Gazette des Hôpitaux*, Feb. 5th.

TREATMENT OF OSTEOMYELITIS.—In one of the forms of epiphyseal ostitis, the inflammation of the spongy tissue of the epiphyses gives rise to very marked softening of the substance of the bone. The course of the disease may be arrested in the following manner: After careful palpation has revealed the point at which the softening of the bone is most marked, a scalpel is freely introduced in this situation; a simple puncture of the skin is made, but the knife is entered boldly and deeply. In osteitis, the skin and the compact tissue of bone are merely punctured, but the areolar osseous tissue is freely incised, since this is in danger of being strangulated by the compact tissue which surrounds it. After this operation the improvement and cessation of the pain are almost instantaneous, as after incision of a felon. A dressing of cotton batting is then applied. The same operation may be resorted to in place of trepanation of the mastoid process, which is indicated so frequently in purulent discharges from the ear. The mastoid process is carefully examined in order to detect a point which is less resistant than the surrounding parts, and the scalpel is then plunged in to a depth of one or two centimetres. Sometimes a discharge of pus,

but often merely blood escapes. In either event, however, the inflammation subsides, and the discharge of pus from the ear ceases. The pain is instantly relieved.—Dr. Guerin, *Journ. de Méd. et de Chirurg.*, March, 1879.

RETENTION OF URINE CURED BY METALLO-THERAPEUTICS.—The patient, an hysterical woman, 40 years of age, had been treated for several years for permanent spasm of the neck of the bladder, metritis and marked hyperæsthesia of the left ovary. During last year she had retention of urine lasting five months and necessitating the daily use of the catheter. This was finally relieved by the use of antispasmodics and suppositories of belladonna. Last November the retention reappeared in a more distressing form than previously. The introduction of the catheter gave rise to a spasm of the urethral muscles and to intense smarting pain; it often produced an hysterical convulsion, attended with loss of consciousness. The patient would not drink for two or three days in order to delay the introduction of the catheter. Metallotherapeutics were then resorted to. It was found that the application of gold to the skin increased the convulsive movements of the limb to which the patient was subject, while other metals, such as copper, steel, and silver, caused their immediate disappearance. Burg's armatures, composed of the latter metals, were then applied to the vesical region and around the upper part of the thighs; an hour later, the patient urinated freely and without pain. After this, the catheter was not again introduced; if the discharge of urine was delayed, the armatures were applied, and micturition was then performed naturally, sometimes, however, with some pain.—Dr. Dupuy, *Journ. de Méd. et de Chirurg.*, March, 1879.

A CASE OF BÉRIBÉRI.—Béribéri is an affection which occurs especially in warm climates, is either sporadic or endemic, and usually attacks the colored races. It begins with general weakness and a feeling of great oppression; this is frequently combined with anasarca, multiple serous effusions, and motor and sensory disturbances, following an ascending course. There are two principal varieties, the dropsical and the paralytic forms. The dropsical form predominates in South America, but the paralytic variety may also develop there as shown by the history of the following patient: He is now 31 years of age, was born of French parents in South America, and lived in France from his seventh to eighteenth years. He then returned to Brazil. Three years ago he suffered from an affection of the liver and spleen. Eighteen months ago the patient became affected with weakness of one leg, which soon extended to the other; he suffered from slight but frequent pains in the legs. Two months later, the upper limbs became involved in the same manner, and the patient was confined to his bed; the left side was more affected than the right. These symptoms were soon followed by anorexia, difficult digestion, constipation, vertigo on turning around; no cephalalgia. The attending physician made a diagnosis of béribéri and advised his return to France. In January, 1877, I found the patient in the following condition: all the limbs were almost equally atrophied; the feet are in forced extension; the paralysis of the legs is almost complete on both sides. The thighs are somewhat atrophied but retain considerable muscular power. The muscles of the legs do not respond to electricity. There is marked paralysis and atrophy of the forearms, especially on the left side: slight diminution of tactile sensibility is observed. The muscles of the arms,

shoulders, and neck are not involved; special senses and intellectual faculties normal. January 10th, a succession of large vesicles, resembling herpes, appeared on the left side; February 2d, a second eruption appeared in the same position and lasting a week; February 16th, a third crop; February 19th, spontaneous pain over the ulnar nerve, in the course of which the eruption had appeared. The patient's condition remained *in statu quo* until the following June, when he began to mend slowly but progressively, and in July of the following year he was able to walk very readily, and had gained considerable flesh.

In the majority of cases the disease begins with numbness, stiffness, pains and deformities in the lower limbs. In the mixed forms, the limbs atrophy, œdema develops, the skin becomes dry and wrinkled; intelligence is preserved.

Various theories have been advanced to explain this affection, but none have proven satisfactory. In my opinion it is due to a lesion of the spinal cord, the nature of which must be determined by future investigations.—M. Laboulbène, *Gaz. des Hôp.*, No. 26-27, 1879.

OVIOTOMY—A SERIES OF FIFTY CASES.—An addition to the statistics of ovariectomy, consisting of a series of fifty cases, has been given by Schröder (*Berl. Med. Woch.*). With one exception, all the operations were performed in the lying-in hospital. Lister's method being strictly adhered to. Of these cases seven, or fourteen per cent., ended fatally; three of the patients dying with symptoms of septicæmia. If no septic germs enter the abdominal cavity, the most dangerous case, Dr. Schröder thinks, may be expected to terminate favorably; but this is not always possible. In two cases of pregnancy the operation was successful, and the procedure is strongly advocated during the early months of pregnancy, because by this means the woman will be spared the dangers of a complication of gravidity and ovarian tumor, and the child is not exposed to greater risks. In one instance a cyst, the size of a man's head, was complicated by a solid tumor of the sacrum, and thrombosis of the left crural artery. The patient survived the operation, and soon recovered. The base of the tumor was once stitched to the abdominal wound to prevent retroflexion of the uterus. Small tumors present more difficulties than larger ones. If the tumors are uncommonly large, the abdominal walls are over-stretched, and the peritoneal cavity is almost empty. This may be the cause of infection through the air entering, and carrying with it zymotic germs. To prevent this it is advisable to draw the intestines into the pelvic cavity, and cover them with the omentum. Where the shortness of the mesentery prevents this, the relaxed abdominal walls should be pressed into the true pelvis. In two cases portions of the abdominal walls were removed, but without producing any particularly favorable result.—*The London Medical Record*, March 15th.

A STRANGE FACT.—Dr. A. E. Goodwin, of Rockford, Ill., writes: "In your journal of the 29th March, page 312, 'A Strange Fact' reminds the writer of a similar one in practice some twenty-six years since in the State of New York—a child born with but one hand. The one wanting corresponded to that of a bachelor boarder in the same tenement-house, who had a stump from amputation at the wrist. Strange to say, such is emotion affecting the organic functions or changes of nutrition of foetus through changes in the mother's blood."

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, April 26, 1879.

THE NEW NATIONAL HEALTH BILL.

THE discussion of the Senate bill for the prevention of the introduction of contagious diseases in the United States has been to some purpose, as is shown in the bill recently presented to the House by Mr. Casey Young. Preserving the main features of the original one by Mr. Harris that of Mr. Young adds some new provisions which will tend to make practicable many of the measures that were previously proposed. For instance, as a proper starting-point, the sum of six hundred and fifty thousand dollars is appropriated for sanitary purposes, to be disbursed under the direction of the board. On a previous occasion, when commenting upon the bill of Mr. Harris, we maintained that it would be virtually inoperative for the want of a suitable sum of money to carry out the provisions of the act. That objection is now met by the appropriation in question, and gives a practical bearing to all the measures calculated to prevent the appearance of contagious disease or arrest its progress when once started.

The scheme of legislation which is proposed in the bill now before us, like the one of Mr. Harris already noticed, contemplates in general terms the national sanitary supervision of all vessels engaged in the transportation of goods or persons from any foreign port, where any contagious or infectious disease exists, to any port of the United States. All such vessels, before their departure from any infected port, are required to have a certificate of health from the consul or health officer appointed by this government, and cannot, under penalty of a heavy fine, enter any port of the United States either to land passengers or cargo.

It is also provided that the National Board of Health collect and diffuse such information on matters of health, and shall advise local authorities of the course to be pursued in times of danger from

epidemics, and in cases of necessity shall confer on said local authorities extraordinary powers to remove incompetent health officers, establish quarantine in sea-ports, and, inland, to erect suitable buildings along river and railroad routes for the disinfection of persons and baggage, and, with the aid of the different State authorities, to use every means to prevent the dissemination of contagion.

These powers are sufficiently ample, if they can be properly carried out, to meet the requirements of the greatest emergencies. The only trouble will probably be in reconciling State's rights with those of the general government. The States claim the constitutional right of protecting their citizens, as to health and property, personal liberty, and the like, and are jealous of any interference on the part of the general government with these functions. It would appear, however, that every precaution is taken to guard against any misuse of power on the part of the new board. In fact, without the co-operation of the State authorities, it would be virtually powerless for any real good in times of emergency. But there is a power behind that of the written law which will be felt when the real necessities of the hour become apparent, and that is, a general public opinion in favor of measures for protection. It is more than likely that everything will be done to aid the board in their efforts in preventing the spread of disease. The people at large will be too much interested in their own safety to listen to anything which does not contemplate the enforcement of even stringent regulations, and no State or municipal government will care to object to the published recommendations of a health board that is supposed to speak with authority on sanitary subjects and is believed to possess arbitrary power for the enforcement of their recommendations. Especially will this be the case when this board has the necessary amount of means at its disposal to aid local authorities in making sanitary reforms, in establishing quarantines, and in the construction of buildings for disinfecting purposes.

The desire for safety will be paramount to all other considerations, and it is more likely that the board will be upheld even in the exercise of what might at other times appear to be unwarranted authority, than that there should be any disposition to trammel its movements.

In the provisions of the new bill are enumerated the inspection of cattle arriving at or exported from the different shipping ports of the United States, also the investigations into the contagious and infectious diseases of said cattle, and the general dissemination of information regarding the same. These are commendable features in the bill, and may be made perfectly feasible by employing suitable experts to investigate and report. At this time there is a special need for some trustworthy statements not only in reference to the actual existence of certain cattle diseases

throughout the country, but of their relative prevalence in different quarters.

In conclusion we would say that the bill of Mr. Young is thus far the most comprehensive in its details, the most reasonable in its provisions, and the most likely to meet with the endorsement of the profession and the public of any which has heretofore been presented to the Legislature. It is difficult to see how it could be improved in any way to meet the necessities which are likely to arise the coming summer. As an experiment it deserves an impartial trial. It is unnecessary, perhaps, to say that we hope the bill will pass, and give an opportunity of proving, by actual application, principles of sanitary legislation which, from a theoretical standpoint, appear to be so nearly perfect.

HOMŒOPATHY AND MEDICAL INSTRUCTION.

A MEMORIAL has recently been presented to the Legislature of Michigan by the homœopathic physicians of that State praying for the removal of the Homœopathic College from the State University. The petitioners say that the college is an expensive failure, its lack of success being due to the fact that the "allopathic" department is old and well-established, and monopolizes all the best sentiment of the place. In the hospital connected with the department, there have hardly been half a dozen patients. In fact, the institution has not fulfilled the expectations of its friends and can only be continued at an unnecessary cost to the State. It is asked that the college be located elsewhere and the appropriation for it be continued.

In connection with this movement some facts in regard to the status of homœopathic colleges abroad have been developed. The University of Pesth, in Hungary, is said to be the only place in Europe where this system of medicine has a prominent place as a government institution established by law. Here there are two professorships supplementary to the regular course, attendance upon these special courses being elective. The greatest number of students before these professors appears to have been six, and often they have actually had no audience at all. Some time after the establishment of these courses an attempt was made to introduce homœopathic professorships into the University of Vienna. No opposition was made by the established professors, but the homœopathic physicians of Vienna petitioned against the movement, asserting that homœopathy could stand upon its own ground and did not need State aid. A confidence so serene and disinterested as this was not to be disregarded, and the new professorships were not established.

The conclusion to be drawn from these facts is, that whenever homœopathy is allowed to come out and display itself to intelligent students by the side of regular medicine, it very soon attenuates and collapses. On the other hand, it is denied the opportunities that

have been furnished it for the cry of intolerance and persecution which have assisted so materially heretofore. It was, for example, through such opportunities and its co-educational advertisement that the Boston Homœopathic School originated and attained a certain amount of prosperity.

It may be well to remember these facts in connection with the proposed amendment to the national code of ethics, to be discussed by the American Medical Association at its coming meeting. This amendment practically forbids medical men to teach persons who they know will subsequently practise some exclusive system of medicine. We do not believe that this is either just or politic. Its first practical result will be to demoralize and perhaps destroy a well-established and reputable school such as that at Ann Arbor, thus accomplishing exactly what the homœopaths desired when they first got themselves legislated into it. A way would be opened by it also for injuring other institutions in the same manner by legislative interference.

Further, a medical instructor has the right to teach whatever pupils he chooses, provided he teaches what he believes to be true. And a professor's honor and dignity depend not upon his audience but upon what he himself says. He cannot be made a better man by excluding prospective homœopaths from his lecture-room, and neither will such proceeding lessen the number or diminish the prosperity of the followers of dogmatic medicine; but rather the contrary. In fact, the measure would only be embarrassing to teachers, and fruitless of good results in any way.

We need place the question, only on the right of the professor to teach the truth to sinners, and on the ground that it is inexpedient in every sense to enforce an exhibition of what, to a large part of the regular profession and all enlightened outsiders, will appear a gratuitous intolerance. If we believe that no narrow and exclusive creed can live, we need not act as though we feared it might do so, should the slightest apparent help be extended to it.

A SANITARY PROTECTIVE ASSOCIATION.

AN Association under the above name has been formed at Newport, R. I., for the purpose of securing, at a moderate cost, sanitary advice and protection to its members. Such associations have been in successful existence in Edinburgh, but this is the first of its kind in this country. The organization includes an inspecting engineer and a chemist. The members pay an annual due of six dollars, and for this are entitled to have their house inspected by the engineer and an analysis of the drinking-water made by the chemist. By a small additional fee they can obtain similar service for any other houses which they may own. They can also have a report, without fee, upon the sanitary condition of any church, school-house or place of public resort within the city of Newport,

and can have occasional supplementary inspection and advice concerning the dwelling or property in respect of which they are subscribers.

The Association is intended to supplement and not conflict with any public health board. Its object is an excellent one, for it cheapens the cost of thorough sanitary inspection, and will therefore tend to diffuse a wider knowledge and excite greater attention concerning matters of public hygiene.

A NEW BOARD OF HEALTH.

THE State of North Carolina has recently created a Board of Health, with powers which will render it a very useful organization. Six of its members are elected from and by the State Medical Society, and three are appointed by the Governor. Its duties are much like those ordinarily bestowed upon such boards, but it is not given any power in connection with licensing or regulating medical practice, as is done in some Western States. An especially good feature is its coöperation with county boards, which are at the same time created. Through these two forms of organization all matters relating to inland quarantine, vital statistics, and general sanitation, are regulated. The provisions of the bill are very creditable to the wisdom of the medical and legislative bodies of the State.

THE AMERICAN MEDICAL ASSOCIATION.

THE next meeting of the American Medical Association will be held in Atlanta, Ga., commencing May 6th. The programme which has been arranged is attractive; and if the attendance is good, as we hope it will be, the meeting cannot fail to be an interesting and profitable one.

Although the distance from the Eastern and Middle States will probably prevent the attendance of a large majority from those districts, the proportion will be made up by delegates from the South and West. The president's address will doubtless be an eloquent and suggestive one, and amply repay the thoughtful attention which we confidently bespeak for it. From all accounts, the work in the sections will be of rare scientific value, while the reports from the different committees will be of unusual interest. The strictly business portion of the meeting will be comparatively unimportant, unless the Association insists upon passing the proposed amendment to the Code, forbidding the teaching, in regular medical schools, of prospective homœopathic practitioners. We hope, however, that this will not be the case, as such a course, if taken by the Association, will certainly stultify it, not only in the eyes of the profession, but of the public at large.

INEFFICIENCY IN EXPERT TESTIMONY.

IN a report upon certain medico-legal cases by Dr. Thad. M. Stevens, the bad state of affairs that still

exists in connection with expert testimony is very clearly shown. Experts who are ignorant, experts who lack common sense, and experts who are dishonest, are referred to in the illustrative cases cited. We have before commented on this and shown, as is done by Dr. Stevens, that, while there are many points in toxicology not yet satisfactorily worked out, yet the present trouble does not lie in the incompleteness of the science, but in the present method of calling experts, some being retained by the prosecution and some by the defence.

The first case given, in particular, shows what an ingenious expert can do when under the stimulus of a fee from the defence. A woman received a potion from her husband and a few hours afterward was taken with convulsions and died. The defendant's expert admitted at first that the symptoms covered nearly all those of strychnine-poisoning. In addition he had received privately the glass from which the potion was given, and found strychnine still in it. He did not mention this fact, however, but testified that though the symptoms were much like those from strychnia-poisoning, they might have been due to morphine—a drug the woman had been in the habit of using, and one whose effects sometimes resembled those of strychnine. He asserted that no strychnine was found in the stomach, but omitted to mention that morphine might obscure the test. In fact, the exhibition, from a scientific point of view, was truly a grotesque one; but the defendant was acquitted. Other cases of like character are given, but such things are too well known to need further illustration here.

The only remedy, and it is a simple one, is to have a commission of experts appointed by the court; they can then work without bias, and can produce evidence that is not contradictory and that does not make themselves ridiculous and their science inefficient. The existence of much false and stupid testimony has now become a glaring fact, of which we have had some very interesting instances in New York, and the present pamphlet should help to awaken some practical efforts for reform in the matter.

TWELFTH ANNUAL REPORT OF THE ST. FRANCIS' HOSPITAL for the year ending December 31, 1878.—This report is printed, as usual, in German and English, and it shows a very active service during the past year. 1,651 cases were treated, of whom 208 died, making a mortality of about 12 per cent. This large mortality is due to the fact that the hospital admits many moribund and incurable cases, more than 100 dying of phthisis alone; 32 fractures and 5 dislocations were treated, the most frequent of the former being those of the clavicle (7) and of the radius (7). Ovariectomy and kolpo-cystotomy were each performed once. There were seven cases of hernia, of which five were operated on. Two cases of median lithotomy and five of external urethrotomy are also recorded.

Reports of Societies.

PHILADELPHIA COLLEGE OF PHYSICIANS.

REGULAR MONTHLY MEETING, FEB. 5, 1879.

(Reported for THE MEDICAL RECORD.)

THE EARTH-TREATMENT OF TUMORS.

DR. ADDINELL HEWSON presented a paper on a case of fibroma of the uterus undergoing cystic degeneration, which he had treated by the external application of a paste of clay and water.

The patient had been suffering for six years from a steadily growing tumor in her abdomen, which was first detected after a suppression of menses consequent upon her bathing in the Hudson river on the second day of the flow. This suppression had continued ever since, and had been attended by severe and constant pains in the loins and inguinal region. Dr. Hewson saw the patient for the first time on October 20, 1878, at a relation's house in Philadelphia. She was propped up in bed, suffering from great dyspnea and exhaustion, and with the tumor so large and projecting that she could not see her knees. The integument covering the tumor was in a state of marked hypertrophy, and was constantly weeping a watery fluid. The vulva was excessively œdematous. The patient's bowels were regular, but micturition was abnormally frequent. Before the tumor appeared she weighed 107 pounds, and when Dr. Hewson saw her, 165 pounds, showing that she had gained 58 pounds in weight in spite of the general emaciation apparent.

All that was done at the first visit was to apply a paste of clay and water, one and a half pounds of the former to three-quarters of a pound of the latter, so as to completely cover the tumor, retaining the dressing *in situ* with a thin layer of cotton batting. This application was followed by marked relief. The urine was examined on the day following, and found to be free from albumen, but heavily loaded with phosphates.

The dressing was then renewed, the same quantity of clay and water being used and the same covering of cotton wadding. Upon this occasion a four-inch roller was run round the waist and a loop of the same breadth fastened to this waist-band well back in the lumbar region on both sides, after having carried it under the tumor close to the symphysis pubis, thus affording the needed support.

On the next day the patient was so much improved that a physical examination was made, with the following results: great tympany under the ribs on the left side; then, below, to a line corresponding with the umbilicus, whilst the patient was sitting up, distinct succussion as of a fluid confined to that portion of the peritoneal cavity; there was then the dulness and feeble succussion, or jelly-like movement, belonging to fibro-cystic tumors, extending down from the line of the peritoneal fluid, and confined to the central portion of the belly, as though there might be a fibro-cystic growth from the body or fundus of the uterus. This growth was evidently extensively bound down by peritoneal adhesions below.

The patient continued to improve steadily under the treatment employed, so that measurements made with a strong tape-line on December 14th, showed that between that date and October 21st, the circum-

ference of the body at the xiphoid cartilage had decreased from 36 to 31 inches, and at the umbilicus from 48½ to 41½ inches; that the distance from the umbilicus to the xiphoid cartilage had decreased from 12 to 9 inches; the distance from the umbilicus to the symphysis pubis from 17 to 12 inches; the distance from the umbilicus to the right anterior spine of the ilium from 16½ to 12½ inches; and the distance to the left anterior spine from 15 to 12¼ inches; that the circumference three inches above the umbilicus was 41 instead of 48½ inches, and three inches below the umbilicus, 42 instead of 46 inches.

During this time the patient had been walking about her room, sleeping comfortably on both sides, and even dressing herself with a silk dress which she had not before been able to make meet on her person for more than two years. She was also perfectly confident of her complete recovery.

During the Christmas holidays she very imprudently walked over nine squares on Chestnut street, and became so exhausted that she had to go into a store for rest. Two days after, there was some œdema of her right foot and her urine became scanty, but it contained no albumen. From this time she grew steadily weaker, notwithstanding the free use of stimulants and fluid nutriment, and finally died from exhaustion on Saturday, February 1st, at 12 P.M.

At the *post-mortem* examination, when the abdominal walls were separated from their adhesions, a number of fibrous cysts were found, from the size of a goose-egg down to that of a pea, in a state of collapse and empty of fluid. The peritoneal surface of the abdominal walls, at those parts where the integument was hypertrophied, was singularly coated with a product in a state of evident degeneration. Upon cutting along the linea alba above the umbilicus, a large cavity containing twenty pints of a brown serous fluid was found. The viscera were all pushed up under the ribs, and the liver was shrivelled. The tumor was bound by broad bands to the liver and diaphragm.

The specimens were examined microscopically by Dr. Morris Longstreth, who furnished a report, of which the following is an abstract: "Tumor fibro-cystic, with firm, jelly-like feeling, covered with thick shining capsule, and connected by a short, flat pedicle to the fundus of the uterus. It was adherent to the abdominal walls below and to the right of the umbilicus, and also connected with the fundus of the gall-bladder. These adhesions contained large arterial and venous trunks, in whose walls were partly encircling, calcareous plates. The gall-bladder contained some biliary concretions, and the cystic duct was closed. The tumor was adherent to the omentum, which was shrivelled and devoid of fat. The uterus was slightly elongated, and its tissue was flabby and atrophied. On its peritoneal covering were found two pea-sized fibroid nodules. The ovaries were small and nodulated.

"A section of the tumor showed that its consistence varied greatly, as did its color, only limited portions showing the usual aspect of fibroid tissue. Numerous bloody points were seen, and many large and small, cyst-like, rounded areas. A microscopical examination of the tumor sufficiently established the undoubted fibroid nature of the growth."

The tumor and fluid removed weighed, the former 27½ pounds, and the latter 20 pounds, making a total of 47½ pounds, which was in striking contrast with the weight of the patient before the appearance of the tumor (107 pounds), and her weight when Dr. Hewson first began his treatment (165 pounds), thus showing a loss of weight of some 104½ pounds to be put down

to the credit of the earth-treatment. Perhaps even a larger loss in the actual weight of the tumor might be claimed, since the patient was very much emaciated when she first came into Dr. Hewson's hands.

NEW YORK ACADEMY OF MEDICINE. OBSTETRIC SECTION.

Stated Meeting, March 27, 1879.

DR. SALVATORE CARO, CHAIRMAN.

THREATENED MAMMARY ABSCESS.

DR. O'SULLIVAN referred to a case in which, by the local application of extract of belladonna, he had prevented the formation of a mammary abscess.

DR. CARO remarked he had noticed in several cases that when belladonna was applied to one breast the pupil upon the *same* side became widely dilated, while the pupil upon the opposite side remained unaffected. He had also noticed that dryness of the mouth was confined to the side upon which the belladonna was applied.

DR. POST remarked that he had applied belladonna locally for the relief of frontal neuralgia, with the result of dilatation of the pupil upon the *opposite* side.

DR. CARO suggested that the nearness of the application might explain such a result.

CAULOPHYLLUM.

DR. SELL again referred to the beneficial effect produced by the fluid extract of caulophyllum for the relief of pains during the latter months of pregnancy.

UTERINE HEMORRHAGE AND INJECTIONS OF HOT WATER.

DR. POST referred to his recent favorable experience in the use of hot-water injections for the arrest of uterine hemorrhage—the water having a temperature from 110° F. to 120° F.

OBSTINATE URTICARIA.

DR. JOEL FOSTER referred to a case of urticaria which had resisted a great variety of treatment. Partial improvement had taken place under the use of quinine and dilute hydrochloric acid—a general tonic plan—pepsin, and various remedies, but the disease continually recurred.

DR. POST suggested a bath containing $\frac{3}{4}$ iv. of sulphuret of potassium to an ordinary bath-tub of water.

DR. CARO suggested the use of hyposulphite of soda in doses of five grains three times daily.

UNCHANGED CAPSULES OF QUININE.

DR. FOSTER mentioned an interesting fact in connection with the exhibition of quinine in the case reported. The patient was first attacked by the urticaria in the eighth month of pregnancy. On the fifth day before her confinement she had a decided chill, and the temperature rose to 106° F. He at once gave twenty grains of quinia in capsules. Forty-eight hours afterwards she had a second chill. The stools, which were semi-fluid, were examined, and found to contain the capsules unchanged. The quinine was then administered in powder, and the chills did not return.

A RECTUM PACKED WITH PILLS.

DR. POST referred to a case of obstinate constipation, in which the rectum was found blocked by a solid fecal mass, requiring the scoop for its removal. When examined it was found to contain hundreds of pills.

PILL FOR RELIEVING CONSTIPATION.

DR. FOSTER suggested as a remedy for constipation a pill containing:

R. Rhubarb (Turkey)..... gr. iij.
Carbonate of soda..... gr. i.
Ipecac..... gr. ss.
Oil of anise..... gtt. v.
M.

To the above one or two grains of pil. hydarg. might be added at times with benefit. The pills should be taken at night.

CHEMICAL AND MICROSCOPICAL DIFFERENCES IN MILK FURNISHED BY THE RIGHT AND LEFT BREAST OF THE SAME WOMAN.

DR. CARO then read a paper in which was reported several cases in which he had noted microscopical and chemical differences in the milk from the right and from the left breast of the same person. In all his cases the milk from the right contained a very much greater amount of nutritive material than that from the left breast.

On motion the paper was referred to the Academy, and the Section adjourned to discuss nutrition from another standpoint.

CHICAGO MEDICAL SOCIETY.

Regular Meeting, March 17, 1879.

DR. E. INGALS, PRESIDENT, IN THE CHAIR.

DR. E. L. HOLMES read some notes on

ATROPIA, DUBOISIA, ESERINE, Pilocarpine, and Muscarine

as used in ophthalmic practice.

Atropia solutions frequently irritated the eyes, notwithstanding the addition of sodic sulphate or morphia, and a new mydriatic was desirable.

Hyoscyamine and ex. hyoscyamus were unreliable.

Duboisia was first obtained by Dr. Wecker, of Paris, in March, 1878; it was the product of a South Australian tree. Dr. Holmes had only seen two specimens. He had substituted it for atropia in a case of keratitis, in which prolonged use of the latter had caused great irritation of the conjunctiva and swelling of the lids. These symptoms at once subsided with the use of the duboisia—gr. i., aquæ ʒ ij.

According to Wecker and others, duboisia possessed the property of dilating the pupils and paralyzing the accommodation even more promptly than atropia.

Eserine and pilocarpine caused contraction of the pupils and spasm of the ciliary muscles. Patients under their influence could see objects only relatively near—just the opposite of the effect of atropia. The influence of eserine and pilocarpine was much less durable than that of atropia. The solution of pilocarpine was more durable than that of eserine, and was also reputed to be less irritating to the eye.

Eserine had been used with benefit in glaucoma, staphyloma, and conical cornea, ulcer of the cornea with or without hypopion, where the iris had been engaged in penetrating wounds or perforating ulcers of the cornea. It had been claimed that it reduced suppuration of the conjunctiva and inflammation of the nasal duct and sac.

While atropia was supposed to dilate the vessels of the eye, eserine contracted them. These two alkaloids were dangerous in iritis.

He had used muriate of pilocarpine in two cases of

keratitis punctata, often an obstinate disease. Speedy relief without irritation resulted.

In a case of staphyloma with increase of tension, and in one of conical cornea with ulceration and conjunctivitis, but without tension, this agent had relieved active symptoms. In three cases of ulcer of cornea with conjunctivitis, no benefit followed its use. The solution for local use had been gr. iv. to aquæ $\frac{3}{4}$ j.

Muscarine was one of the active principles of poisonous mushrooms. It was a syrup-like alkaloid, without color, taste, or smell, soluble in water. It caused spasm of the apparatus of accommodation. It contracted the pupils variably in different individuals. By union of muscarine and atropia, dilatation of the pupil and spasm of the ciliary muscles might be produced at the same time.

Muscarine in poisonous doses arrested the heart's action; atropine tended to neutralize the effects of muscarine on the heart. Atropine in doses of $\frac{1}{10}$ of a grain should be administered at intervals to patients who had taken poisonous mushrooms.

DR. F. C. HOTZ said the continued use of atropine tended to reduce tension of the eye and cause softening of the tissues. Frequently the solution pained the eyes and reddened the lids. He related some illustrative cases. He believed pilocarpine was the remedy of the future.

DR. LYMAN WARE said in one case of glaucoma he had used pilocarpine with benefit.

DR. HOLMES thought there was great danger, in the use of pilocarpine, that the existence of iritis might be overlooked and injury done.

DR. R. G. BOGUE reported the following case of

TRACHEOTOMY FOR TUMOR OF THE LARYNX.

A boy, ten years old, in July, 1875, caught a cold, which persisted with cough and expectoration of mucus, with occasionally slight difficulty of breathing. He lost flesh, and the obstruction of breathing by November became quite troublesome, and was worse while sleeping. Dr. H. A. Johnson found, with the laryngoscope, ulcer of the top of the epiglottis, and in the left aryteno-epiglottic fold a small tumor, which folded that side of the epiglottis downward and toward the median line, obstructing the respiration, especially when the laryngeal muscles were "off their guard," as in sleep. A twenty-grain solution of sulphate of zinc was atomized, with a hand-instrument, into the throat every two or three days; an alum gargle was ordered, and quinine. The case grew worse, and tracheotomy was performed January 2, 1876. The zinc solution was still applied, but with a post-nasal syringe. Improvement followed, except that the tumor did not disappear. In May he had whooping-cough, during the continuance of which the tumor diminished, and in two months was nearly gone. During this time he was taking iodide of potassium. In October only a slight nodule remained, and the tube was removed. The boy still had and has a partial loss of voice; he is only able to speak in a tone between a whisper and the ordinary voice.

There was no evidence of hereditary syphilis in the case.

DR. BOGUE also reported a case of

PHLEGMASIA DOLENS, WITH AMPUTATION OF THE LEG—THE CASE SIMULATING POPLITEAL EMBOLISM.

Mrs. —, æt. 24, healthy, was delivered of her first child February 18th. The labor was natural, and nothing unusual occurred till the 23d, when the severest pain appeared in the calf of the left leg. This required for its relief large doses of morphia—half a

grain being given at a time hypodermically. Moderate swelling of the leg and in the popliteal region occurred, with some tenderness. In three days the ball of the foot and side of the great toe became discolored; this appearance, with coldness and loss of sensation, rapidly extended up the limb, so that by March 5th the leg was gangrenous from its middle downward. The leg was only slightly swollen, and the foot was shrunken.

Pulsation of the femoral artery just below Poupart's ligament was quite feeble. The long saphenous vein was neither distended nor tender. There was now (the first day Dr. B. saw the case) no particular odor from the limb. The limb was kept very warm, and the patient stimulated slightly, and fed with nourishing food. By March 7th the gangrene had reached to within five inches of the knee. Spells of very severe pain continued. The lochia had ceased. No discomfort had been complained of in the pelvis. By the 14th a line of demarcation was apparent just below the knee. On the 16th amputation was made at and through the knee-joint. The soft parts at the seat of operation were firm from sero-plastic effusion. Lateral flaps were made, and secured through their anterior two thirds; posteriorly they were left open for drainage. The soft tissues of the popliteal space were divided at about the middle of the space. At this point the artery was patulous, but small; it was unobstructed "as far down as it was examined, which was beyond where it breaks up." It must have been unobstructed upward, for it throbbed well after ligation. Two popliteal veins and all the deep veins were full of firm clots, the subcutaneous ones alone being free. The clots in the deep veins did not extend "above where the internal saphena joins, for this was unobstructed." The patient recovered, notwithstanding some burrowing of pus in the thigh. Two weeks after the operation a phlegmasia dolens of the other limb came on, which, however, was not severe.

The case was clearly one of phlegmasia of the deep veins of the leg. Dr. B. regarded it as a very rare form of the disorder. Gangrene occurred from the sudden complete obliteration of a large part of the venous system of the leg.

DR. R. PARK and DR. D. W. GRAHAM presented pathological specimens of bones.

Correspondence.

STILLMAN'S JOINT SPLINT.

TO THE EDITOR OF THE NEW YORK MEDICAL RECORD.

SIR:—I have just read an article in the RECORD entitled "A New Joint Splint, with a Description of its Application to the Knee," in which Dr. Stillman presents to the profession an apparatus for which he claims many advantages, especially in its power to produce fixation and graduated extension in joint diseases. The principles of the application of joint extension appear to be so misunderstood by the writer in advocating the use of his apparatus, that I cannot refrain from calling attention to the article. Without doubt, in certain cases of knee-joint disease, where there is little or no deformity, the brace proposed by Dr. Stillman would be of some use in producing fixation; but in well developed arthritis, whether originating in the cartilage, synovial membrane, or ligaments, I cannot see how it can be of the slightest benefit.

The real indication in joint diseases is absolute rest of the part, together with moderate extension. Any one, on first observing an individual case, must notice nature's exaggerated efforts to meet these indications. Reflex muscular contraction in joint diseases is, primarily, conservative, although it results, if unchecked, in contracture and consequent deformity. How are we to prevent the deformity, and, at the same time, produce equal and moderate extension, together with fixation? The difficulties in devising any practical apparatus for the knee-joint are very great. Here we have the largest and strongest articulating surface, protected by numerous ligaments and surrounded by powerful muscles. Hence, in order to produce extension or overcome deformity, it is necessary to exercise great force, and that, too, continuously for a long time. Not only so, but the direction of the force is a matter of the greatest consequence. It must be exerted in two directions: first, in the line of the deformity, *i. e.*, extension of the joint; second, in opposition to the deformity, *i. e.*, extension of the contracted muscles. If we view the instinctive muscular contraction as primarily conservative, we must graduate our extension of the muscles by our extension of the joint. Now, it is impossible to fulfil these indications with the instrument devised by Dr. Stillman, inasmuch as, from its construction, it can do no more than overcome by a steady pressure the excessive flexion. And this action must be more of disadvantage to the diseased part than of benefit. We are aware that one of the chief troubles after operation for false ankylosis at the knee-joint (*brisement forcé* of Bauer) is the inflammation consequent upon the pressure together of diseased articular surfaces, since all the force used in breaking up the adhesions is expended upon the joint, which must necessarily be the fulcrum of the lever. And if this be the case in the comparatively short time of operation, how much more must it be true when the knee-joint is made the fulcrum of long-continued lever-force.

The distinction between extension of the knee-joint and extension of the leg, has evidently not occurred to the doctor.

Now, a word as regards the apparatus itself. The doctor designs producing extension and counter-extension of the limb by means of two strips of steel, connected at the knee by a compound ratchet-bridge, and fastened to the thigh and leg by leather and metallic girths, or by plaster-of-Paris. He relies on the natural conformation of the thigh to produce counter-extension, direct extension being produced by riveting the apparatus to the shoe. It would almost seem as if the doctor had never made use of the instrument he has designed, for an application of it, according to his description, would be very difficult. The natural conformation of the thigh will allow counter-extension, but only when the constriction of the limb is very excessive. The tissues of the middle and lower thigh are very yielding, and the close application of the apparatus to overcome this tendency would amount to almost virtual strangulation. After some little time there would necessarily occur a great deal of atrophy in consequence. This would be so especially in case plaster-of-Paris were used, since its well-known tendency to contract on setting would make it almost impossible to obtain an accurately fitting surface. Had the doctor designed uniting the adhesive plaster with the plaster-of-Paris in such a manner as to make extension and counter-extension with the adhesive plaster, the desired action would have been much more certain.

Again, the use of the slotted strip does not seem to

present the same facilities for graduated extension, nor so much certainty of retaining it, as the usual arrangement of the ratchet and key. In the latter case we have the extension-power directly under our control, with no possibility of its slipping away; while the method of unloosening slot-screws and pulling the lower part of the brace down seems very rude and inaccurate. Moreover, any one who has ever applied extension to the knee-joint, and is aware of the tremendous force necessary to accomplish it, would look upon the doctor's plan as futile. The only result accomplished would be the breaking of the plaster-of-Paris under the strong pressure. The truth of the matter is that braces, in most cases of chronic inflammation of the knee-joint, cannot meet the desired indications. Operation, either tenotomy, *brisement forcé*, resection, or amputation, according to existing conditions, seems to be the best known method of treating these chronic deforming diseases. In cases after operation, where fixation is necessary for a length of time, the instrument devised by Dr. Stillman might be of service, although, even in such cases, either Sayre's splint or the continuance of the plaster-of-Paris would meet the same indication, and be much more simple.

Yours truly,

JOHN R. HOBBS.

211 EAST 13TH STREET, April 7, 1879.

NATIONAL BOARD OF HEALTH AND HOMEOPATHY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—I see by the papers that the President has included among the members of the National Board of Health the name of Dr. Verdi, of Washington. Is he not the homeopath whose appointment, some years ago, as member of the Washington Board of Health caused such an excitement in the local Medical Society? Was not Dr. Bliss disciplined for consulting with Dr. Cox, whose offence was sitting in the same board with Dr. Verdi? Really, we think that the American Medical Association should, at its approaching session, take notice of this, even if it be necessary to propose a new amendment of the Code as was done last year to cover the case of the Michigan University.

Yours respectfully, X.

MEDICAL REPORTS IN THE NEWS-PAPERS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—It cannot, of course, be supposed that the surgical staff of Charity Hospital were cognizant of the presence of "a chiel among them takin' notes" for the press on the occasion of Dr. Howe's recent operation for the transfusion of human milk, or that they were responsible for the publication, in the *World* of April 13, of a *verbatim* report of the professional colloquy over the case—a column in length, under the large-capped heading "A New Thing in Surgery." Naturally, none of the gentlemen concerned in the performance could suspect that the "large concourse of spectators" was not altogether of a medical character, or that a surgical procedure, in itself neither difficult nor uncommon, would furnish material for a newspaper sensation. But, in view of the inevitable ubiquity of the modern reporter, and the apparent inability of our metropolitan surgeons and physicians to exercise any control over the selection of their audiences, I would submit the expediency of persuad-

ing the American Medical Association to rescind that clause of the Code of Ethics which prohibits "to publish cases and operations in the daily prints, or suffer such publications to be made; or to invite laymen to be present at operations." This and sundry other sections of the said Code have long been proven incompatible with the practice of several of our most prominent practitioners, and if the public at large insist upon having stenographic details of everything said and done by a favored few of our brethren, whether in college lectures, papers before presumably private societies, or "interviews" touching esoteric medical theories, the respect for the will of the majority on which our whole system of government rests (to say nothing of our own reputation for consistency), should induce us to at once remove such mere verbal obstacles to the gratification of the public demand.

I am, sir, yours, etc.,

Sic nos non nobis.

APOMORPHIA IN CYNANCHE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—At an early hour on the morning of Feb. 17, 1877, I was called in great urgency to see the infant son of Mr. B. F. J—, one of my *clienteles*. The father, who had come for me in person, to insure my immediate attendance, while I was dressing gave me the following condensed history of the case: The child, which was about two years old, had complained slightly the day before, and even the night previous to that; but the parents, being young and inexperienced, "thought it was nothing but a cold," and paid no attention to a series of symptoms (as detailed by the father) that would have excited the fears of older and more experienced persons. "Last night," added the father, "the little fellow did not seem to be so lively as usual, and was a little fretful; but, beyond a *mening* sort of a cough, we never noticed anything wrong with him. He slept with his nurse in the next room to his mother and myself, but, though the door was open between us, neither of us knew that there was anything serious the matter until I went into the room a few minutes ago and found him in spasms and choking to death." On arriving at the house, which was distant but a half-block from my office, I found my little patient in a truly alarming and pitiable plight. He was lying on the bed, the head and trunk drawn far backward, with marked opisthotonos. The face was cyanosed and livid, the hands clenched, and from between the firmly-set teeth slowly exuded a frothy mucus. The struggle for breath, the gasping, whistling effort to inhale the air, was simply horrible, and it was plain that unless relief was very prompt the combat could not be maintained much longer. Death was near at hand. I had in my hypodermic case a solution of hydrochlorate of apomorphia, containing one per cent. of the salt, and without hesitation I injected five (5) minims of it under the skin of the arm. I then directed the father to take the child in his arms and hold him face downward, and, with my watch in hand, I awaited results. In two minutes and fifty seconds, almost without an effort, copious vomiting came on and a membranous cast of the larynx and trachea was expelled. *Per saltum*, as if by magic, the terrifying and urgent symptoms disappeared, and a new lease of life was taken by my little patient. The subsequent treatment of the case I need not detail here, the patient making a quick recovery.

My object in transcribing the above is to emphasize

the statement made by Ellis (Diseases of Children, Wood's Library Ed., pp. 104-5), that "apomorphia is an excellent emetic in croup, in doses of one-fortieth of a grain"—though the dose used by me was double this amount.

FRANK L. JAMES, Ph.D., M.D.

OSCEOLA, ARK., April 18, 1879.

ERGOT IN THE TREATMENT OF PNEUMONIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Having noticed articles in recent numbers of the RECORD, on the treatment of pneumonia in Bellevue and the Episcopal hospitals, with, in the former, a rather discreditable mortality, I am induced to make known, through the RECORD, a remedy which, to my knowledge, has not previously been employed in the treatment of this disease, and which, in ten cases, has yielded better results than any other treatment.

The value of ergot in hæmorrhage from the lungs has long been appreciated, and, from its therapeutic action, I have for years been persuaded of its equal efficacy in pneumonia; but not until this winter did I venture to depart from the "orthodox" treatment and employ it.

In all of the ten cases the "rusty" sputa was speedily and permanently arrested, and the attack in half the cases aborted; in the others, so shortened as to recover in six or seven days.

This remedy acts as promptly in pneumonia as in hæmoptysis, whether used hypodermically or "per ora," and in a few hours arrests the "rust" by relieving the intense congestion on which it depends.

I usually combine it as follows:

℞. Fl. ext. ergot.	f. ʒ iv.
Tr. digitalis.	f. ʒ j.
Plumbi acetatis.	gr. vj.
Aqua cinnamomi.	ad. f. ʒ ij.

M.

Sig. Give a tablespoonful every two hours until bloody sputa stops—then twice a day.

I begin the treatment by an antipyretic dose of quinine—from 40 to 60 grains—which, in connection with the ergot mixture, equalizes the pulmonary circulation, relieves the congestion and inflammation, and the patients recover in about half the time required by other modes of treatment.

Firmly believing that this treatment far exceeds all others in its rapidly beneficial results, I present it to the profession for trial. Respectfully,

J. T. WELLS, M.D.

BAKERSFIELD, CAL.

PERINEAL AND UTERINE LACERATIONS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Reflex uterine action as a cause of perineal and cervical lacerations is being more clearly recognized now than ever before. Our advance in physiology enables us to deal more intelligently with nature's processes in parturition where this reflex force is an important factor for good or evil, and for evil of course, when a laceration occurs. My attention was called to this subject in attending a primipara in premature labor at the seventh month. On entering her room, I supposed I was almost too late, as she was having the characteristic pains that attend the passage of the head through the outlet. On examination I found

the bag of water pressing strongly against the perineum and os externum, but in the interval that the dilatation of the os uteri was not over one inch, it being a case of polypoid prolapse of the membranes. At the next pain I ruptured them, with the effect of stopping the expulsive effort, and the labor went on with the ordinary dilating pains. Now, what was the cause of the expulsive effort? Why, simply reflex action caused by pressure of the bag of water on the perineum. This being the case, it brings up that questionable practice of supporting the perineum to prevent laceration, when that very pressure or support by reflex action increases the expulsive effort and makes a laceration more imminent. Under such support, "secundum artem," is it any wonder that Simpson should have been chagrined at the number of perineal lacerations that occurred in his practice, and when unwittingly the preventive means proved to be the cause of the disaster? Though formerly taught to support the perineum, I now *religiously* let it alone, merely restraining too quick advance by direct pressure on the head, thus causing it to recede between pains when it would not otherwise do it.

That we should assist nature in all cases, and beware of meddling interference, brings me to notice the cause of lacerations of the cervix. That they are often the result of reflex force I am quite certain, and that the extra force that causes the laceration is generated by a too early rupture of the membranes. Physicians are so often impatient of delay that, to expedite matters, they rupture before there is full dilatation. At first nature seems somewhat surprised at the intrusion, and makes a short halt, but head-pressure brings her to her senses through reflex action, and the pains are largely increased in force, and with this increase comes a laceration of the cervix. When pains are deficient in power the os may be irritated by pressure with the finger, without rupturing the membranes, which should be left intact till nature ruptures them, or indicates that she has not power to do so.

J. M. WARD, M.D.

CORNELIA, MO.

New Instruments.

A DOUBLE CANULATED NEEDLE.

By D. A. CURRIE, M.D.,

ENGLEWOOD, N. J.

This is a new instrument; it is of very simple construction, consisting of two hollow, curved needles, with bevelled points, and handles attached, as may be seen by Fig. 1, in the accompanying woodcut, which shows the instrument *closed*. Fig. 2 shows it open, with the suture passed through the needles. The intention was to use wire sutures only, but reference to Fig. 1 shows a thread (so to speak) about to be drawn through by means of a fine flexible hook, thereby inducing the introduction of silk sutures perfectly easy.

The general *modus operandi* of this instrument will immediately suggest itself to the gynecologist and surgeon without my entering more fully into detail. However, I hope the brethren will not rate me an enthusiast when I claim that a very important desideratum has been attained in the completion of the double canulated needle for several reasons, *viz.*, it saves much valuable time and patience; it renders the operations of vesico- and recto-vaginal fistulas com-

paratively easy. Both (edges or lips) are transfixed at exactly opposite points, just where they are desired, and simultaneously, and without distortion of either lip.

It is so perfectly adaptable in general shape, size, etc., as to be used within very small compass. It also

Fig. 2.

Fig. 1.

twists the suture when wire is used. The only parts of the operation that the skilful manipulator cannot do with it, is to cut the wire or to pare the edges of the fistula. In twisting the suture, unnecessary strain upon the tissues should be prevented by means of a tenaculum, held so as to protect them. The following case of lacerated cervix uteri will corroborate my statement:

The lady had suffered from extensive laceration to the right and left, with cystic ectropium of the cervix left since the birth of her last child, five years previously. The general pelvic ache and neuralgic pains from which she suffered during menstruation were excessive. Shreds of a membranous appearance would also be thrown off during this time, accompanied with a very offensive fetor, which would continue until menstruation ceased, when both the shreds and offensive odor would disappear.

The uterus was much hypertrophied, and retroverted in about the second degree; its depth was three and a quarter inches, with a glairy *mucopurulent* discharge almost constantly from the distorted os. She was subjected to local treatment for three months, by which the general condition of the organs was improved, and an operation for the repair of the laceration was performed in the usual manner, with this exception, that the *double canulated needle* performed a very important part of the operation; the result of which was complete union, leaving to all appearances a virgin os.

Within the short space of four months the womb was reduced to two and three-quarter inches in

depth, the pelvic ache and neuralgic pains had almost disappeared, together with the shreds of membrane and accompanying fetor.

She at present is, to use my own language, "perfectly well."

In conclusion, I safely say that, after having tested this instrument in a case of recto-vaginal fistula with equally gratifying results, I feel warranted in giving it this strong recommendation to the medical fraternity in general, and the gynecologist in particular.

The instrument was made for me by Mr. Stohlmann, of Geo. Tiemann & Co., New York.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from April 6 to April 19, 1879.

JANEWAY, J. H., Major and Surgeon. Detailed as member of the Retiring Board in session in New York City, vice Surgeon J. H. Bill, hereby relieved. S. O. 92, A. G. O., April 16, 1879.

O'REILLY, R. M., Capt. and Assist. Surgeon. Relieved from duty at Charleston, S. C. (post discontinued), and to accompany the command to McPherson Barracks, Atlanta, Ga. S. O. 63, Dept. of the South. April 11, 1879.

ELBREY, F. W., Capt. and Asst. Surgeon. Relieved from duty at Oglethorpe Barracks, Savannah, Ga. (post discontinued), and to accompany the command to McPherson Barracks, Atlanta, Ga. S. O. 63, C. S., Dept. of the South. Granted leave of absence for six months on surgeon's certificate of disability. S. O. 89, A. G. O., April 12, 1879.

HARVARD, V., 1st Lieut. and Asst. Surgeon. To accompany 18th Inf. to Fort Assiniboine, and on arrival to be relieved from further duty there and return to Dept. of the South. S. O. 35, C. S., Dept. of Dakota.

REED, W., 1st Lieut. and Asst. Surgeon. Leave of absence extended 15 days. S. O. 38, Div. of the Pacific and Dept. of California, April 9, 1879.

PERLEY, H. O., 1st Lieut. and Asst. Surgeon. Relieved from duty at Fort Pembina, to proceed to Bismarck, report for duty to Commanding Officer 18th Inf., accompany that regiment to Fort Assiniboine and take station at that post. S. O. 35, Dept. of Dakota, April 12, 1879.

PRESBYTERIAN HOSPITAL.—ELEVENTH ANNUAL REPORT.—There have been 555 cases treated in the hospital during the past year, with a mortality of 7.02 per cent. An exceptionally large number of important surgical operations are recorded. Nineteen tumors were removed, including an epithelioma of the tongue and sarcoma of superior maxilla. There were two lumbo-colotomies, an excision of hip, ligation of lingual and femoral arteries, lithotripsy, etc. A very complete report is given by the pathologist, Dr. Satterthwaite.

ST. MICHAEL'S HOSPITAL.—ANNUAL REPORT, Newark, N. J., Jan. 1, 1879. This hospital, with a capacity of between 70 and 80, has treated 891 patients during the past year, its out-door department including over 5,000 more. Two amputations of the thigh, partial removal of lower jaw, removal of tumor from the neck, are some of the more important operations performed.

Medical Items and News.

CONTAGIOUS DISEASES.—WEEKLY STATEMENT.—Comparative statement of cases of Contagious Diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending April 19, 1879.

Week Ending	Typhus Fev.	Typhoid Fev.	Scarlet Fev.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fev.

REDUCED RAILWAY FARE TO ATLANTA, GA., FOR THE DELEGATES OF THE AMERICAN MEDICAL ASSOCIATION AND THEIR FAMILIES.—The Piedmont Air-Line (Penn. Central, by way of Richmond, Danville, Charlotte) offer tickets from New York, and return, for \$37.25. Pullman car all through, and for the delegates only, if a sufficient number apply. Two through trains daily, leaving Jersey City at 10 P.M. and 8.20 A.M., to arrive at Atlanta in thirty-eight hours. On Sunday no morning train. Passengers leaving by 10 P.M. Saturday, 3d May, may stop ten hours on Sunday either at Washington or Richmond, take the express train in the evening, and arrive at Atlanta 10.30 P.M., on Monday, the 5th May: a good arrangement as to convenience and seeing the scenery of the country.—Apply J. L. Waldrop, Gen. East. Passage Agent, 8 Astor House, New York.

PRIZE OF THE ALUMNI ASSOCIATION OF THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.—This prize of \$500, for an original essay on some subject connected with medicine or surgery, is open only to the competition of the Alumni of the College of Physicians and Surgeons of New York. The conditions upon which the prize will be awarded are as follows: 1. The subject is left to the option of the competitor. 2. The essay must present sufficient original experimental or clinical observation to make it a useful contribution to medical knowledge. 3. The essay, designated by a motto, must be sent to a member of the Committee on Prize Essays, accompanied by a sealed envelope, inscribed with the motto, and containing the name and address of the author, on or before February 1, 1880. Committee: A. Brayton Ball, M.D., 38 West 36th St.; T. A. McBride, M.D., 12 East 28th St.; Robert F. Weir, M.D., 37 West 33d St.

THE DEATH-RATE IN RUSSIA.—In the year 1877 Russia seems to have had the heaviest death-rate of any country that keeps mortality statistics. According to the recent report of the Medical Bureau, in a population of eighty millions deaths occurred at the rate of from 30 to 50 per thousand. Diphtheria caused the largest mortality, next typhus, and then small-pox.—*Lancet.*

TAPE-WORM IN A CHILD AGED TWENTY-TWO MONTHS.—Dr. N. R. Derby, of Bergen Point, N. J., writes: I notice in the RECORD of Jan. 18, 1879, the report of a case of tape-worm in a child three years old. Having had recently a case still younger, I send particulars for your disposal.

Baby H— was 22 months old when the mother noticed that the passages were studded with white patches, and at times almost entirely composed of

them. At length becoming alarmed, she brought me some of these specimens for examination, which I found to be pieces of *Tenia solium*. The child lives near by, and was under my observation nearly every day. It seemed to be in perfect health. The following was ordered given on an empty stomach:

R. Ext. felicis liq.	℥xxx.
Syr. zingib.	ʒij.
Mucil. trag.	ʒij.
Aqua.	ʒj.
M.	

One-half to be given for a dose and repeat. This brought away patches of two and three feet in length for a time. As the pieces began to appear again after a few weeks, pumpkin-seed tea was freely given while the child was fasting, followed by castor oil. This was efficient, and brought away twenty feet and the head. Adding to this what the parents had already secured and saved at my request, I find by measurement forty-five feet, and the parents are confident that at least half that much was lost before the child was brought to my notice.

DR. GEORGE B. WOOD'S BEQUESTS.—The will of the late Dr. Wood has just been admitted to probate and contains, among numerous other items, the following: His pathological cabinet he leaves to the Medical Department of the University of Pennsylvania, with the understanding that it is to be under the immediate supervision of the Professor of the Theory and Practice of Medicine, and that the sum of \$200 is to be appropriated annually for its preservation and repair out of the increase of the money left to the University.

The bond and mortgage of the College of Physicians, which he held, amounting to \$5,000, he presents to the society. He also bequeaths to it all his books on science and medicine, and appropriates the sum of \$10,000, the income of which is to be employed in paying the salary of the librarian of the society, and in heating, lighting, and repairing its building.

\$50,000 are left for the permanent endowment of the Auxiliary Faculty of Medicine in the University of Pennsylvania. His medicinal plants he leaves to the Medical Department of the University of Pennsylvania, placing them under the care of the Professor of Materia Medica and Therapeutics, and \$5,000 is set apart for the construction of a botanical garden and conservatory as an adjunct to the same chair.

\$75,000 are bequeathed to the University Hospital, for the foundation of a free ward of twenty beds, to be called the "Peter Hahn Ward," in memory of his father-in-law.

The Children's Hospital and Philadelphia Dispensary receive \$5,000 each.

A certain part of the income accruing from the cranberry lands, in New Jersey, belonging to Dr. Wood, is to be invested yearly in the name of the University of Pennsylvania, and when this investment amounts to \$500,000, it is to be divided, half going to the medical department and half to the other departments—law, academical, and scientific—of the University.

In consideration of his numerous bequests to this institution, it is stipulated that all patients from Cumberland Co., New Jersey, up to a certain limit, applying for treatment at the hospital, shall receive such treatment and their beds and board in the wards gratis.

STEVENS' TRIENNIAL PRIZE, 1882.—This prize, established by Alexander H. Stevens, M.D., amounts to two hundred dollars. The subjects for the next prize are as follows:

I. *Lesions of the Brain, in connection with the two Forms of Diabetes.*

II. *Diphtheria, in its Relations to Membranous Croup.*

The competing essays, on either of the above subjects, should give an account of our present knowledge, and also the results of personal investigation. They must be transmitted to the President of the College of Physicians and Surgeons, New York, on or before the first day of January, 1882. Each essay must be designated by a device or motto, and must be accompanied by a sealed envelope, bearing the same device or motto, and containing the name and address of the author. The envelope belonging to the successful essay will be opened, and the name of the author announced at the Annual Commencement of the above-named College, in March, 1882. This prize is open for universal competition.

J. C. DALTON, M.D.,

Secretary of the Commission.

DIASTASED IRON.—This latest pharmaceutical novelty is prepared by soaking cress seeds in a solution of iron. The seeds of course absorbed the solution and begin to sprout. The process is then stopped, and the seeds dried and sugar-coated. Diastase is of course formed when the seed begins to germinate. Arsenic and iodide of potassium are diastased in a similar manner.

NUTRITIVE VALUE OF PEPTONE.—At a meeting of the North-western Medical and Surgical Society, held March 19, 1879, Dr. George B. Fowler gave a preliminary report upon the results of recent researches undertaken by him regarding the alimentary value of digested meat. The results of his experiments are very satisfactory, and look towards the introduction of peptone as the proper nutritive material in cases where hitherto such adventitious substances as beef-extracts, milk, and blood have been resorted to. It is especially adapted, Dr. Fowler maintains, for intra-venous injection, and his successful experiments upon animals were verified by a trial upon the human subject. This important and practical matter will be more fully elaborated in a paper shortly to appear.

THE ADIRONDACK REGION AS A THERAPEUTICAL AGENT IN THE TREATMENT OF PULMONARY PHTHISIS.

(Read before the Medical Society of the State of New York.)

By ALFRED L. LOOMIS, M.D.,

PROFESSOR OF THE THEORY AND PRACTICE OF MEDICINE IN THE
MEDICAL DEPARTMENT OF NEW YORK UNIVERSITY, N. Y.

PART II.

CASE VII.—Miss C—, aged eighteen, in the spring or early summer of 1875 reached the Adirondacks in a very feeble condition. She had had a cough for six months, with frequent pulmonary hemorrhages, attended by fever, loss of flesh and strength. Physical examination of the chest revealed dullness on percussion, bronchial respiration, and crackling râles at the apex of the right lung. Her improvement began at once; at the expiration of three months she had gained eleven pounds in weight, had no cough, and had so regained her strength as to be able to take active out-of-door exercise. In early fall she returned to her home, and has there remained in good health.

In this case the pulmonary consolidation was evidently catarrhal in its nature, and of recent date. That she came to the Adirondacks in the earlier stages of the disease probably had much to do with her rapid and complete recovery.

CASE VIII.—Mr. B—, aged thirty-two, with a decided hereditary predisposition to phthisis, took up his residence in the lake region of the Adirondacks in the summer of 1875. After he left home, before he reached the Adirondacks, he had a severe hemorrhage. For three months after his arrival he was in a critical condition, had severe cough, frequent hemorrhages, fever, and rapid emaciation. He did not begin to improve until late in the fall, after which time his improvement was steadily progressive. During a two years' residence in the region he fully regained health and strength, his cough ceased, and in August, 1878, I could find no trace of disease in the lungs, except old pleuritic thickenings and adhesions at the apex of the left lung. In September, 1878, he left the Adirondacks.

During his first year's residence in the Adirondacks no physical examination was made, but he stated that previous to his coming into the region his medical advisers had told him that his lungs were extensively diseased, and that he had come with a "forlorn hope." His disease commenced as a "severe cold," and unquestionably his case was one of catarrhal phthisis.

CASE IX.—Dr. T—, aged thirty-two, with marked hereditary tendency to phthisis, came to the Adirondacks in the summer of 1875. For ten months he had been ill with well-marked phthisical symptoms. The upper third of the right lung was consolidated, with circumscribed liquid râles in the supra-scapular fossa. At the apex of the left lung there was exaggerated rude respiration, but no râles. He remained four months, in camp the greater portion of the time. As he improved he became restless, and could not be induced to longer remain. His weight was now 148 pounds; he had gained twelve pounds, and had no cough. After leaving the Adirondacks he went South, but returned in the spring in a most enfeebled condition; weight 127 pounds, with pallid countenance, difficult breathing, and so weak that he was

obliged to lie down the greater portion of the time. The entire upper lobe of the lung on the right side was consolidated, and abundant râles were heard throughout the consolidated portion. The respirations at the apex of the left lung had become markedly bronchial in character. He began to improve, and by the first of December had regained his appetite and strength. Again he became restless, left the Adirondacks, went to Colorado and California, was twice near death, and in early summer returned to the Adirondacks "in extremis," with a large cavity in his right lung, and commencing softening in his left lung. Having thrown away his chances for recovery, he died in early winter.

A series of mistakes marked the course of this patient. A short time previous to his death he stated to me that in attempting to follow the advice of his Philadelphia physician, who recommended a warm climate, and that of his New York medical adviser, who recommended a cold climate, he had made the result a failure.

As we review his history, it seems to me that we are warranted in coming to the conclusion that the result might have been different had he remained in the Adirondack region for the two or three years succeeding his first visit.

CASE X.—Mrs. M—, aged twenty-eight, with no hereditary tendency to phthisis, consulted me in the fall of 1876. She had a cough which was paroxysmal in character, with little expectoration. For several months she had been losing flesh, had had daily fever and night-sweats; at times she had suffered from severe attacks of dyspnoea, which were followed by an expectoration which she termed "stringy." Physical examination revealed pulmonary consolidation posteriorly at the apex of the right lung, with sharp bronchial râles over the consolidation. At different points over the chest dry and moist râles were heard, and I made the diagnosis of probable fibrous bronchitis, with pulmonary consolidation at the apex of the right lung. I advised her to spend the winter in Asheville, N. C., where she obtained little if any relief. During the winter she expectorated a number of well-formed bronchial casts. On her return, I found her more feeble than when I first saw her, and the area of lung consolidation increased.

Following my advice, in June she went into the lake region of the Adirondacks, remained nearly a year, and entirely recovered from the bronchitis and pulmonary consolidation.

This case was one of well-marked plastic bronchitis, with circumscribed consolidation at the apex of the right lung. When we recall the fact that the majority of cases of chronic plastic bronchitis are followed by phthisis, and terminate fatally, the complete recovery reached in this case is somewhat surprising.

I would call attention to the fact, that in this case the climate of the Adirondacks produced such different results from that of Asheville, N. C.

CASE XI.—Miss F—, aged nineteen, of a non-phthisical family, consulted me in March, 1875, having taken cold the previous January. She was rapidly losing flesh, had an almost constant hacking cough, night-sweats, with other well-marked phthisical symptoms. On physical examination, I found complete consolidation of the upper third of the right lung, with crackling râles posteriorly. Evening temperature 103, and pulse feeble. She had lost ten pounds since January, and was easily exhausted. Ten days after I first saw her she had a profuse hemorrhage; in two days this was followed by a second. She was reduced in strength by these hemorrhages, and her

general symptoms became so aggravated, that unless soon arrested it was evident her pulmonary disease would progress very rapidly, and soon terminate fatally; I feared acute phthisis.

In the early part of April she went to Washington, was carried to and from the cars; she remained six weeks, with very little improvement in her condition, the entire upper lobe of the right lung having now become involved in the pulmonary consolidation. The early part of July she reached the Adirondacks. She rapidly began to improve, and when I examined her the following October, she had gained twenty pounds in weight, coughed only in the morning after rising, had no fever, and had a pulse of 80. Bronchial breathing was heard posteriorly over the area of the pulmonary consolidation, while quite extensive pleuritic adhesions and thickening could be detected in front. She spent portions of the summer and fall months in the Adirondacks for the two succeeding years, and now regards herself perfectly well, and is so regarded by her friends.

The pleuritic changes which occurred during the active progress of the disease alone give evidence of her former pulmonary disease. When this patient first went to the Adirondacks, not only did her disease involve a large amount of lung-tissue, but her general condition was very unpromising, her stomach was exceedingly irritable, and her emaciation was rapid and her anæmia extreme.

CASE XII.—Mrs. P—, aged forty, from a non-phthisical family, first came under my observation in March, 1877. Since 1869, she had suffered with phthisical symptoms; at times her case had been regarded as hopeless. Physical examination revealed fibrous induration of the upper lobe of the right lung, with the physical signs of cavity under the right clavicle, and pleuritic thickening over the entire lung. Pulse 100, feeble and easily accelerated. Temperature 101° ; extreme dyspnœa consequent upon exertion. She had night-sweats, was extremely anæmic, not markedly emaciated, but her weight was less than when in health. Cough paroxysmal and violent, with slate-colored expectoration; her appetite was capricious, and her disease had made marked progress since the early part of January. In early summer she went to the lake region, where she remained until fall. In her general health the improvement was very marked; but little change took place in the physical signs. During the winter there was little change in her condition. Early the following summer (summer of 1878), she went to the Adirondacks and into camp, where she remained until the following October. Not only was the improvement in her general health very marked, but her cough almost entirely disappeared, and her general physical condition was better than it had been since the commencement of her disease. The fibrous induration remained at the apex of the right lung, although vesicular breathing could be heard over the remaining portion of the lung.

When I first examined this case I regarded it as one of fibrous phthisis, and only hoped for that complete cicatricial process to be developed which renders the diseased lung-tissue inactive. While, as yet, she has not reached such a condition, her steady improvement without any new lung-tissue becoming involved, and the absence of any evidence that degenerative processes have been developed in the lung-tissue already involved, leads me to believe that if the same climatic influences be continued, which during the past two years have produced such beneficial results, at length the desired result may be obtained.

CASE XIII.—Mr. S—, aged thirty-one, with a

good family history; at my suggestion went to the Adirondacks in the early part of the summer of 1876.

He first consulted me in the fall of 1875, had then been ill about one year; had well-marked phthisical symptoms. He had received a most unfavorable prognosis from medical men in this country and in Europe. A physical examination revealed quite extensive consolidation of the apex of the right lung, with sharp crackling râles. I advised him to spend the winter in Asheville, N. C. On his return in early summer, I found that although his general condition had somewhat improved, his pulmonary disease had made considerable progress. Soon after his arrival in the Adirondacks he was seized with an acute cystitis, which prostrated him very much. Although he remained nearly two years in the lake region, his pulmonary disease steadily but slowly progressed. In the spring of 1878, in an extremely debilitated condition, he returned to his home in Ohio.

In this case, the disease from its onset steadily progressed, and the diagnosis of tubercular phthisis which was made the first time I saw him, was confirmed by his subsequent history. While he was in the Adirondack region, although at times he seemed to be improving, the periods of improvement were of short duration, and each exacerbation of fever left him in a more and more enfeebled condition. With each exacerbation of fever, new areas of lung-tissue became involved. At the time he left for his home in Ohio, suspicious bubbling sounds were heard over the original seat of his disease, and his respirations were amphoric in character.

CASE XIV.—Mr. L—, aged twenty-two, with well marked phthisical symptoms, had been ill six months, when, in the summer of 1877, he took up his residence in the Adirondacks. At the time of his arrival his cough was constant, his expectoration was of a greenish color, and of tenacious consistency. He was rapidly losing flesh, had night-sweats, and shortness of breath upon slight exertion. Physical examination revealed consolidation at the apex of the right lung, with fine crackling râles in the supra-scapular fossa. He remained about one year, spending the summer and early fall in camp. His cough disappeared, and he gained fourteen pounds in weight. Ten months after his arrival no abnormal sound could be heard in his lungs, except feeble respiratory murmur, and pleuritic creaking at the end of a full inspiration at the former seat of the pulmonary consolidation. He has continued perfectly well to the present time, and is now studying law. This was a case of catarrhal phthisis in its first stage, in which, like the previous case of which I have made mention, the recovery from the pulmonary disease was rapid and complete.

CASE XV.—Mrs. G—, of a non-phthisical family, first consulted me in April, 1878. She had suffered with well-marked phthisical symptoms for six months, the result of a cold contracted the previous summer while she was in a debilitated condition, which had been followed by a cough. Physical examination of the chest revealed consolidation of the upper two-thirds of the right lung, with circumscribed moist râles under the right clavicle with amphoric breathing. She was very feeble; had rapidly lost flesh; had night-sweats, loss of appetite, an almost constant cough, an abundant expectoration, with occasional spitting of blood, and dyspnœa upon slight exertion. Temperature in the evening, 103° ; pulse, 110 to 120.

She went into the lake region of the Adirondacks in June, and returned the last of September. She made little or no improvement until the last of August; from that time she began to rapidly improve,

and has continued to gain flesh to the present time. She now weighs 38 lbs. more than before she went to the Adirondacks, and coughs only in the morning. Physical examination shows vesicular breathing over the seat of the former consolidation, except posteriorly, where the breathing is broncho-vesicular in character, and pleuritic creakings are well marked. No signs of cavity can be detected.

The improvement in this case did not commence until two months after she reached the Adirondacks; in fact, for a time the disease seemed to be progressing with some degree of rapidity. During this time she had two quite profuse hemorrhages. The changes in the diseased lung were so extensive, and of such a nature, that I did not hope for recovery. The increase in weight has been greater and more rapid than in any other case of phthisis which has come under my observation.

CASE XVI.—Mr. R—, aged thirty, of a phthisical family, began to cough in the winter of 1876. Two months after he began to cough he had a hemorrhage. Soon after the hemorrhage he began to have fever and to lose flesh. He first consulted me in May, 1876. He then presented the appearance of one in advanced phthisis. He was emaciated, had an evening temperature of 102° and 103° , and had great difficulty of breathing, becoming exhausted from the exertion attending the ascent of a flight of stairs. Physical examination revealed extensive consolidation of the upper lobe of the right lung. Distinct bronchial respiration could be heard from the clavicle to the upper border of the fourth rib. He went into the Adirondack region, where he remained a year. On his return to New York he presented the appearance of perfect health. He had no cough, and said he weighed more and felt stronger and better than he had for years. Physical examination revealed only pleuritic thickening over the former seat of the pulmonary consolidation. No physical examination of the chest was made from the time he went into the Adirondack region in early winter until his return to New York, one year later. He stated that his improvement commenced about three weeks after he reached the Adirondacks, and that every day during the winter months he spent from six to eight hours out of doors.

He has remained in New York until the present time, and has had no return of his phthisical symptoms.

CASE XVII.—Mr. A—, aged thirty-one, with a strong hereditary tendency to phthisis, had his first hemorrhage in Feb., 1877, after which he rapidly lost flesh and strength, and in June, when I first saw him, he was extremely emaciated and anæmic; had a constant hacking cough, with muco-purulent expectoration, and frequent slight hemorrhages. Temperature ranged from 100° to 103° ; pulse never below 100, and easily accelerated. Physical examination revealed slight consolidation at both apices, with moist, bubbling râles in left supra-scapular fossa. He went to the Adirondacks in July, and remained nearly a year, during which time his disease slowly but steadily progressed. A physical examination in July, 1878, revealed a cavity at the apex of left lung, with intiltration of the entire left lung. I advised his return to his family.

In this case the diagnosis of tubercular phthisis was made at the first examination. The subsequent history and the uninterrupted progress of the disease fully sustained the diagnosis first made.

CASE XVIII.—Mrs. O—, aged thirty-four, with no hereditary predisposition to phthisis, first consulted

me in May, 1878. She had coughed for six months, had repeatedly had hemorrhages. She went south during the winter of 1877–1878, where she did badly, rapidly losing flesh and strength, and had afternoon fever and night-sweats. Pulse 102° F., feeble and easily accelerated. Afternoon temperature 102° . She complained of dyspnoea on slight exertion, and became easily fatigued, was anæmic, had no desire for food, and was dyspeptic. A physical examination revealed consolidation of the upper third of the left lung, with bronchial râles and pleuritic adhesions over the entire left side.

In July she went to St. Regis Lake (Adirondacks), where she remained three months. Immediately she began to improve; the cough became less and less troublesome, her appetite returned, and she soon gained 14 lbs. in weight. By the first of September her pulse and temperature were normal, and by the first of October the only physical evidences of disease were slight pulmonary consolidation under left scapula, and pleuritic creaking in left infra-clavicular space. She has continued to improve since her return, and is now apparently well.

This was another case in which the rapid and continued improvement was unexpected. The general appearance and condition of the patient when first seen by me was unpromising. The perseverance or fixedness of purpose, and good sense of the patient, I believe had very much to do with her marked improvement. She remained out of doors nearly the whole of every day, took no risks, and made use of everything in her surroundings which would aid in bringing about the desired result.

CASE XIX.—Mr. M—, aged thirty-four, consulted me in the spring of 1877, having had a pulmonary hemorrhage. For the previous three months he had been rapidly losing flesh and strength, had fever, night-sweats, and was extremely anæmic. He had had cough with expectoration for more than a year. Physical examination revealed consolidation of the apex of the left lung as far as the lower border of the third rib, with quite extensive pleuritic changes and marked retraction of the left side of the chest. He had repeated hemorrhages, was confined to his room for several weeks, and it was the latter part of June before he was able to travel. Early in July he started for the Adirondacks. He presented the appearance of a person in advanced phthisis, and physical examination at this time detected marked retraction of the left chest and bronchial dilatation in the left supra-scapular space.

During July and August his improvement was very slight, and it was the latter part of August before he was able to go into camp. He remained about two months in camp, during which time he regained his normal weight, his strength returned, and he had great physical endurance. Late in the fall he returned to New York, presenting the appearance of one in health, although he still had cough and shortness of breath, and physical examination showed little change in the consolidated lung. His improvement continued until the following March, when he again grew worse, lost flesh, and had occasional fever. In May he had another slight hemorrhage. An examination of his chest showed an increase in the pulmonary consolidation since the previous examination; pleuritic adhesions and thickenings were detected over the whole of the left side, with more marked retraction of the left side. He again went to the Adirondacks, and remained in camp the greater portion of the summer and fall. He rapidly regained flesh and strength, and all his active phthisical symptoms again disap-

peared, excepting morning cough with expectoration. Little change could be detected in his physical signs. Unquestionably, this is a case of fibrous phthisis, and although while he remains in the Adirondacks he regains his flesh and strength, and the progress of the disease seems to be arrested, yet little or no improvement can be detected in the diseased lung.

CASE XX.—Miss H.— had her first pulmonary hemorrhage, which was quite profuse, in January, 1877. Within the week following this first hemorrhage she had frequent hemorrhages, averaging more than one per day. During the preceding year her physical and mental labor had been unusually taxing or severe, and she was not in her usual health. For several months she had suffered more or less from nasal, pharyngeal and bronchial catarrh. She first consulted me in June, 1877, at which time she presented all the symptoms of well-developed phthisis. She had constant cough, with muco-purulent expectoration frequently streaked with blood, was emaciated, had fever, night-sweats, loss of appetite, shortness of breath, etc.

A physical examination revealed consolidation of left lung from its apex down to the fourth rib, with abundant mucous râles over the left scapula. In the early part of July she went into the Adirondacks, and into camp. On her return from the region in November, I found her much improved; she coughed little, had no fever, had gained eight pounds in weight, could walk long distances without fatigue or shortness of breath. Physical examination showed marked diminution in pulmonary consolidation in the left infra-clavicular space; bronchial respiration and mucous râles were still heard over left scapula. She steadily improved until the middle of February, when she had a severe attack of influenza, from the effects of which she did not entirely recover, and June, 1878, found her in a worse condition than she was in June, 1877. Following the influenza, a pleurisy was established over the whole of the left pleura. This greatly increased her difficulty of respiration. June 11th she again left for the Adirondacks, went into camp July 1st, and remained in camp until October 20th. During the summer she had two slight hemorrhages, but she steadily regained her strength and weight, and seldom coughed. A physical examination, made the following November, showed entire absence of pulmonary consolidation at the apex of the left lung, and the only remaining physical signs of disease were pleuritic adhesions or thickenings over the upper third of the lung, with localized bronchial râles in the left supra-scapular fossa. Since November her improvement has been steadily progressive, she has the appearance of one in health, yet she has slight cough with muco-purulent expectoration; and physical signs of disease are still present.

The statement previously made in regard to the probable effect of a longer stay in the woods, holds true in this case.

A brief summary of the foregoing cases gives the following results:

Of the twenty persons who have tested the therapeutical power of the climate of the Adirondack region, by giving it an extended trial, ten have recovered, six have been improved, two have not been benefited, and two have died.

The ten cases of recovery were those of catarrhal phthisis; of the six cases in which improvement took place, four were those of catarrhal phthisis, and two were cases of fibrous phthisis. The two cases in which no benefit was received from a stay in the region were cases of tubercular phthisis, in both of which the dis-

ease steadily progressed, and at no time could it be said that it was even temporarily arrested. In both cases of fibrous phthisis, extensive retraction of lung had taken place, with bronchial dilatation and compensatory emphysematous developments. Exercise could not be taken, for very slight physical exertion brought on attacks of severe and frequent dyspnoea, and the severe attacks of coughing interfered with digestion and nutrition. In both cases, failure of the right heart was well marked. In both, the improvement manifested itself in the gaining of flesh and strength, rather than in any change in the lungs which could be appreciated by physical examination. I believe these cases would have done better in Colorado.

Those cases of catarrhal phthisis which were improved but not cured were those in which the pulmonary changes were extensive, or had reached the stage of excavation—cases in which complete recovery is always problematical.

In all these cases the improvement did not commence immediately—not until some time after the individual had taken up his residence in the region; and when it did commence, it was not constantly progressive. Each case had a long history of getting better and worse, but each advance toward recovery was more marked than the former. Whether these cases will or will not reach complete recovery is a question, but I am certain that a permanent residence in the region greatly increases the probabilities of such a result, from the fact that in those cases which have come under my observation a temporary absence from this region has been followed by such sad results. In all the cases of catarrhal phthisis which have reached recovery, either the pulmonary changes were not extensive, or they were of recent origin, and improvement commenced soon after reaching the Adirondacks. The results obtained established the fact that a large proportion of the cases of this variety of phthisis, if they have not passed the first stage, or stage of consolidation, can recover.

The two cases that terminated fatally were cases of catarrhal phthisis. Although, when they came into this region, their lungs were extensively diseased, they were much benefited during their stay, and it seems to me that impatience and imprudence had very much to do with the fatal termination.

Results show that the climate of this region is better adapted to the treatment of catarrhal phthisis than of any other variety. I believe fibrous phthisis does better in higher altitudes—for instance, in Colorado.

My experience leads me to believe that climate has little beneficial effect upon tubercular phthisis.

For some time I have believed—in fact, I became convinced soon after I began to study carefully the effect of climate upon phthisical invalids—that a larger proportion of such were benefited or cured in a cold than in a warm climate.

The testimony of those who have spent a winter or more than one winter in the Adirondacks is, that improvement was far more rapid during the winter than during the summer months; and I have found by physical examination of the lungs, that the arrest in the morbid processes and the establishment of the curative processes was more marked during the winter than during the summer months.

I shall have accomplished my purpose, if by this hastily prepared paper I shall have awakened in my professional brethren the spirit of investigation as regards this extensive health-restoring region within the boundaries of our own State, which we have been passing by, while we have sent phthisical invalids far from home and friends to regions far less restorative.

SCARLET FEVER IN CHICAGO.

By HENRY M. LYMAN, M.D.,

PROFESSOR OF PHYSIOLOGY AND OF DISEASES OF THE NERVOUS SYSTEM, RUSH MEDICAL COLLEGE, CHICAGO.

HAVING lately read in the MEDICAL RECORD an interesting editorial summary of the facts regarding scarlet fever, gathered from a study of its recent prevalence in New York, it has occurred to me that a review of our own experience in Chicago may not be without value.

I have now before me a chart compiled from the official records of the Health Office, which exhibits by the graphic method the course of the mortality from scarlet fever in this city for every month during the past twenty-seven years. It admirably exhibits, with a degree of clearness which no mere columns of figures can illustrate, the uniformity of the action of the laws which control this mortality. In a large community like ours, the disease is always present, but its prevalence, and the consequent aggregate mortality, are strictly dependent upon the existence of a *susceptible* population. During the occurrence of what is called an epidemic, the disease reaches and smites down all, or nearly all, those members of the community who have not previously been rendered tolerant of its influence. The epidemic then dies out like a fire which has exhausted the stock of combustible material. Relieved from the pressure of contagion, the natural increase of population soon furnishes a new quota of susceptible individuals. The expiring embers of the conflagration flame up again, and the disease becomes increasingly frequent until another period of epidemic prevalence and subsequent exhaustion is evolved. This rhythmic course of the mortality from scarlet fever is admirably shown by my chart. It, moreover, brings to light the fact that the periods of greatest epidemic mortality succeed each other with remarkable uniformity at intervals of about seven years. This fact is related to the observation that the most susceptible period of life is between the first and the seventh year. Next to these causes, the greatest prominence must be assigned to the condition of the weather. The disease is partial to cold climates, and its greatest severity is experienced during the coldest months of the year. Excessive weather of any kind always produces an increase of mortality during its continuance. The chart, therefore, exhibits a notable increase of mortality during stormy weather in the spring and fall of the year, or when a period of unusual heat depresses the population during the summer months. Everything, in short, which makes life more difficult in a cold climate, tends to increase the mortality of scarlet fever. This fact is still further illustrated by a reference to the graphic chart. It shows that during times of rapid expansion of the city by immigration the ratio of mortality to the whole population has been greater than during periods of a quiet and natural increase. In other words, just in proportion to the degree in which people become thoroughly adjusted to their surroundings by long residence, or, better, by hereditary descent in the same locality, will their susceptibility to scarlet fever diminish. Consequently, the larger and the older the city, the greater the immunity from scarlet fever.

The effect of governmental intervention for the purpose of limiting the ravages of the disease has been also clearly illustrated by this chart. Previous to the year 1877, scarlet fever had been allowed to take its own course, so far as sanitary authority was concerned. The disease would gradually increase for about a

year, reaching the climax of mortality during the most inclement month of the winter next following the outbreak. It would then begin suddenly to decline—rapidly falling off during the following year, with only such minor exacerbations as were directly attributable to the weather, until about eighteen months after the epoch of greatest severity, when the minimum of mortality would occur. This was always during the most salubrious weather of the early summer. The year 1876 was our last formative period. During the entire year the mortality kept steadily increasing, but with a lower ratio relative to the aggregate population than had been known in previous epidemics, notably, that of 1863, for example. Certain parties who were interested in the sale of alleged specifics against scarlet fever succeeded at this time in getting the ear of the public, and through the connivance of the newspapers, the community was wrought up to a terrible state of excitement about a commonplace epidemic in which it was clearly shown by the extensive investigations of Prof. C. W. Earle and others that the rate of mortality did not exceed ten per cent., and was probably less than nine per cent. The community, however, was beside itself with terror, and the aid of the civic government was demanded. A very worthy and energetic gentleman was made Commissioner of Health; the laws were doctored so as to give him a liberal handful of discretionary—that is, *despotic*—power, and it was announced that within sixty days scarlet fever would be unknown in Chicago. The climax of mortality had been passed, and the epidemic had commenced its usual rapid decline when the new officials were installed. They commenced operations with a stringent vigor that was as magnificent as it was frightful. All physicians were ordered to report every case of scarlet fever, and those who neglected to do so, and could be caught, were heavily fined. Every infected house was placarded with a tremendous red sign, recalling vividly to mind the horrors of the plague in London. There was a great deal of loud talk about confining people to their houses in case of exposure, but this project soon had to be given up, for the simple reason that people would not stay in their houses. Isolation and disinfection were diligently preached, and were carried into practice with unheard of zeal. In fact, we were never before so uncomfortable since the foundation of the city.

Well, what was the outcome of all this pucker? The epidemic went on its accustomed way, paying no more heed to the wrath of man than if it had been a West Indian hurricane. Favored by a remarkably mild summer and winter, during the year subsequent to the climax of mortality, there was less disturbance of its course by fluctuations of the weather than has been sometimes remarked; but, otherwise, its progress was unchanged, and the minimum of mortality was reached just eighteen months after the turning-point of the epidemic had been passed. The mortality then began again to increase, and has been gradually working up ever since, exactly as had been predicted by our eminent ex-sanitary superintendent, the well-known Dr. John H. Rauch. Our chart does not give the slightest sign to indicate that anything has in any way interfered with the natural progress of the disease; and yet a great effort was honestly and earnestly made to "stamp out the epidemic." But human nature is stronger than human law. At first, there seemed to be no escape. When a poor devil found his business destroyed, and the bread kept out of his mouth by a placard on the door of the little den where he lived and struggled to make a living for his wife and chil-

dren, expostulation and entreaty were of no avail. The laws of Illinois were as inflexible and as irrevocable as the laws of the Medes and of the Persians. But the approach of election-time wrought wonderfully to mollify the hearts of the great ones of the earth, so that now, when a big politician finds scarlet fever in the bosom of his family, it is discovered that the laws of Illinois confer large powers of discretion upon sanitary officials; so the odious placard is in such cases nailed against the *inside*, instead of the outside, of the door. From that favored position it is said that it diffuses throughout the entire household a healing influence, which is utterly lost in space when the warning card is displayed in the usual way.

What are the lessons which may be derived from this experience? I will not repeat the conclusions which have been so forcibly set forth by the editor of the *MEDICAL RECORD*. I will only add the following reflections:

I. We may see an illustration of the ineffable folly of trying to ignore the forces of nature and the laws which control the universe. Winds, and rain, and cold, and heat, and the prime causes of disease are beyond the power of man. We can intervene to a very limited degree; and often when we think we do the most, we only defeat our own efforts.

II. We also see the folly of attempting to ride roughshod over the feelings of people. Human nature is stronger than human law; and it soon became evident that a large proportion of the people would not have their houses placarded. This feeling was forcibly expressed to me by no less a person than the highest executive officer of the law, who declared that he would "just like to see anybody put a card on his door." This feeling is based, not merely upon prejudice, but upon an ineradicable feeling of opposition to the interference of government with the private rights and household arrangements of citizens. It is true that a good many thoughtless people—more or less consciously imbued with socialist notions about government—were very much taken with the idea of having other people's houses placarded; but, as a general rule, the only parties who thoroughly enjoy a placard on their own door are the people who have had trouble with their landlord, and consequently welcome scarlet fever in April as a means of getting even with their enemy. These being the facts, it did not take very long for the average doctor to find out on which side his bread was buttered. To their credit, or otherwise, it must not be forgotten that there was among our professional brethren a noble few who, more thoughtful of their duty to the public than of their obligations to their patients, never—well, yes, never—failed to report all their cases of scarlet fever. But, alas, many of us found the diagnosis of the disease surrounded by so many difficulties that often the approach of death alone sufficed to warrant a request for a "warning card."

III. We may learn the folly of attempting to enforce stringent measures in the case of endemic diseases with a comparatively low rate of mortality. It is true that our official statistics record a death-rate of about 24 per cent. from scarlet fever during the year 1878, but outside of the Health Office it is well-known that this is nearly or quite three times the actual rate. Consequently, it was found that the use of warning cards added nothing to the isolation of families suffering the disease. Besides this, owing to the great uncertainty which attends all measures of isolation and disinfection, it was found impossible to generate any widespread and lasting enthusiasm in favor of these latest resources of sanitary art. When people

have burned their clothing, and have renovated their bedding, and have painted and varnished and disinfected everything regardless of expense, and have then seen a child emerging from a most scrupulous quarantine of six weeks after apparent perfect recovery, only to infect all his brothers and sisters, they generally conclude that they would rather let the children take their chances another time. And when other people have seen a single child passing through all the stages of malignant scarlet fever without the slightest attempt at isolation, and without infecting another individual in a large family, they are quite slow to regard scarlet fever as an intensely contagious disease.

IV. The last and most important lesson to be learned from our experience has reference to the proper limitation of the efforts of our sanitary authorities. In every instance where they have undertaken to intrude beyond the line which divides the public life of the citizen from his private relations, they have created evils greater than those they have sought to remove. Instead of the old-fashioned frank confession of scarlet fever with immediate notification of all the neighbors, we now have frequent concealment of cases, with all the petty deception and uneasiness which must grow out of such behavior. I have never met with anything which has done so much to debauch the conscience of the profession as this new method of "stamping out scarlet fever." If the health officers could be content to limit themselves to those functions which alone are consistent with good government, none of these evils would be experienced. Their authority should be supreme over the sanitary condition of all highways, alleys, and public places throughout the city. They may rightfully control the admission of children into the public schools, and should, therefore, seek to obtain the fullest information regarding the existence of contagious disease. They may properly abate all nuisances which endanger the welfare of the public. They may even enter the lobbies of hotels, and the yards and common passage-ways of tenement houses; but they cannot rightfully or wisely proceed a single step beyond the threshold which divides the public life of the citizen from his domestic relations. Sanitary enthusiasts and the inspired apostles of "state medicine" have got to recognize and to respect this line, if they desire any permanent influence with the community. It is their apparent indifference to these distinctions which makes thoughtful people so distrustful of the boards of health and similar associations which just now are so noisy. Unless they can learn these lessons and cease to encroach upon the private rights of citizens, they will as signally fail to accomplish their philanthropic ends as we have failed to stamp out scarlet fever in Chicago. Arbitrary methods can be tolerated—and then with but indifferent results for good—only in communities which have been effectually dragooned into servile subjection to the powers that be, or in regions where long enjoyment of a large measure of liberty has rendered people unsuspecting of the insidious methods by which their freedom is destroyed.

AMYL NITRATE A CARDIAC STIMULANT.—There is an accumulation of evidence that this drug is a prompt and valuable cardiac stimulant. Where a rapid action is desired, it has no equal. Even when inhaled in half-drachm and drachm doses, it has never done any harm. Physicians should overcome their fear in this regard.

A PECULIAR FORM OF CORNEAL OPACITY.

By RICHARD H. DERBY, M.D.,

SURGEON NEW YORK EYE AND EAR INFIRMARY.

THE case that is here presented illustrates an affection of the cornea, of which, so far as I know, an adequate description will scarcely be found in the text books.

The "band-shaped" * corneal opacity extends usually from one side of the cornea to the other, occupying the region exposed when the lids are but half open. It is symmetrical on both eyes, and the rest of the cornea continues quite clear and unaffected. The opacity lies in the superficial lamella of the cornea, the surface of which is sometimes dull; its color is gray or yellowish brown, later on here and there showing white spots. Von Graefe likens its appearance to the effect of smearing across the cornea salve containing some metallic salt.

The beginning † of this affection escapes the notice of the patient. He complains of dazzling, or comes for advice on account of slight failure of sight. There is at the outset, on either the nasal or temporal or both margins of the cornea, a faint opacity. These two regions of cloudiness slowly advance toward each other until they meet; the opacity now gains in intensity, and later on completely masks the subjacent pupil and iris. As v. Graefe shows, in this period it is purely a corneal affection with which we have to do. In a certain class of cases the tension of the eyeball increases, the pupil becomes inactive and dilated, and excavation of the optic disk takes place, as in glaucoma simplex. In another class of cases the pupil resists all mydriatics, the iris is discolored, posterior synechie are formed. With this chronic iritis the opacities of the cornea become more intense, are finely mottled with dark and light dots (consisting, perhaps, of carbonate of lime), and secondary glaucoma may be developed.

The case that is presented here illustrates two different stages of this corneal affection. Patient F. S., aged 54 years, has had trouble with his right eye since childhood. Nearly every year, for a fortnight at a time, the eye has been painful, and the sight gradually failed until about eight years ago the eye was practically of no use to him. More than twenty years ago he had pain in the left eye and lachrymation, but the sight of this eye did not begin to fail until within the last four years. Since then the eye has not been so

strong, and patient has on this account in the last few months been unable to do his work as a mason. During this time he has frequently suffered from temporary obscurations, and has noticed rainbow colors around the lights. The right eye (see woodcut) presents the following appearances. Extending across the cornea and completely hiding the region of the pupil is an opacity containing probably calcareous deposits.

There is occlusion of the pupil and the tissue of the iris is atrophied. There is a faint perception of light, but no projection. The appearance of the left eye is indicated in the drawing, and illustrates a comparatively early stage of the disease. The band-shaped opacity in its upper margin corresponds to the horizontal meridian of the cornea; it is nowhere transparent, and is of a grayish white color; its margins clearly defined and the cornea beyond clear. The pupil dilates moderately well under atropine, but neither after its use or with the stenopæic slit is the vision improved. The vision of this eye is $\frac{1}{150}$. Jæger No. 4 can be read in five inches. There is marked limitation of the visual field upward, inward, and

downward. De Wecker * gives the name of *opacités glaucomateuses* to this corneal affection, which he describes as rare and found only among adults.

Clarke † has published three cases of symmetrical opacities of both corneæ. In two of these the opacity was of a rusty brown color, the deposit appearing to be pigmentary; in the third it was of a calcareous nature. In none of these cases does the author speak of any evidences of secondary glaucoma.

Bowman ‡ speaks of a form of opacity of the cornea which he believes to have its seat in the anterior elastic lamina. He describes it as creeping very gradually from near the border over the surface of the cornea toward the centre. "The epithelial surface retains its smoothness and lustre, and the opacity does not appear to have much depth. Other varieties of opacity, very chronic in their course, and evidently not inflammatory, are liable to form, as I believe, in the same tissue. They may be of a brown tint, with an indefinite margin, and may affect both corneæ at the same time. I am not aware that these are particularly described in books, nor whether they admit of removal or even arrest."

Of the pathology of the band-shaped corneal opac-

ity very little has been written. Recently Goldzieher* had an opportunity to examine an eye whose cornea presented a typical example of this affection. Upon removing the cornea and holding it to the light, here and there in the anterior lamella masses looking like free pigment could be seen. Under the microscope these masses proved to be colloid, lying in the most diverse forms in the superficial layer of the cornea. The corneal epithelium was thickened, and in places showed hyaline degeneration.

In the treatment of this affection von Graefe has pointed out the advantage of an early iridectomy, both in its effect upon the advance of the corneal process and in checking the secondary changes to which such eyes are liable.

CONTRACTED KIDNEY.

By WILLIAM S. ELY, M.D.,

ROCHESTER, N. Y.

(Read at recent meeting of New York State Medical Society.)

MR. PRESIDENT AND GENTLEMEN: The readers of "Ziemssen's Cyclopædia" will, I think, agree that Vol. XV., on "Diseases of the Kidney," is one of the most important of the series, and an able exponent of the most advanced views of kidney pathology.

My own experience has impressed me with the value of Prof. Bartels' article upon renal cirrhosis, in the volume referred to. This is a chronic form of kidney disease, to which the terms "contracted kidney," "interstitial nephritis," "renal sclerosis," and "granular atrophy of the kidney" have been applied by different writers.

Though authorities differ about the mode of production of the pathological condition bearing these names, they agree that the weight of the kidneys is reduced; that they are tougher than normal; that the capsules are often thickened and unusually adherent, and when torn off leave a granular surface. On section the cortical substance is seen to be greatly diminished, and, if the substance of the kidney is submitted to careful microscopic examination, it is found that the tubular structure and its contained epithelium have undergone extensive wasting. In addition to these changes, in every typical case, there is hypertrophy of the left ventricle of the heart, without valvular lesion. Bright noticed cardiac hypertrophy in some of the kidney conditions bearing his name, but its constancy with "contracted kidney" and its significance have been determined by Traube, Bartels, Grainger Stewart, and others. It has been attributed to increased tension in the general arterial system, due to vascular obstruction in the kidneys, and this hypertrophy is deemed as compensatory and conservative as is the case with valvular lesion.

Prof. Bartels has endeavored to prove that contracted kidney, the pathology of which I have just outlined, is often a distinct affection, not necessarily preceded nor followed by parenchymatous nephritis. It is the most insidious and easily overlooked of all chronic kidney diseases. Affecting frequently persons beyond middle life, its beginning is seldom recognized, and the disease may be far advanced before the physician's attention is called to it.

Occasionally the first premonition is a fatal convulsion or an apoplectic fit, and the detection of renal cirrhosis then becomes the work of the post-mortem examination. As a rule, however, certain significant symptoms are present during life. They relate to the

nervous and digestive systems, and to the discharge of an excessive quantity of urine of a low specific gravity. It ordinarily contains a faint trace of albumen, and when the sediment from the entire quantity passed in twenty-four hours is concentrated in a conical glass only a very few hyaline casts may be detected. The patient at this time may be actively engaged in business; he may have the appearance of perfect health, and deem himself only slightly nervous or dyspeptic. A single examination of his urine will not determine the nature or gravity of the case, and it is essential for a correct diagnosis that the entire quantity voided in successive periods of twenty-four hours should be saved for examination, for the quantity may be a most important symptom. So largely increased is it, that the patient often considers himself affected with diabetes. In this opinion his physician may coincide. Many standard works treat of protracted and fatal cases of polyuria, under the head of diabetes insipidus, and class it among obscure nervous affections. Tronseau, Roberts, Dickinson, and others devote chapters to its symptomatology and hopeless tendencies, while upon its pathology they throw little or no light. Since the microscopic examination of diseased kidneys has supplemented the opinions resulting from observations by the naked eye, diabetes insipidus is found to mean renal cirrhosis; and so constantly is this the case, that I desire to raise the question suggested by Dr. Loomis, whether there is any such condition as diabetes insipidus terminating fatally without renal changes, and, I will add, without renal contraction? I cannot better call attention to the ideas which I am able only to summarize in this paper than by the recital of two cases, the first of which illustrates a frequent, and the second an exceptional, form of contracted kidney.

In June, 1876, Mr. ———, sixty-nine years old, a well-preserved man, of fine physique and healthy appearance, weight 194 pounds, consulted me for dyspepsia and irritable bladder. A specimen of urine then examined was slightly albuminous, but no casts were found. My next note of this patient is a year later, June 11, 1877. He had had faintness, and dull headache, with slight blurring of vision. On June 14th I measured the quantity of his urine for twenty-four hours, and found he had passed 54½ ounces, acid, specific gravity 1010. There was the faintest trace of albumen, and a few hyaline casts were obtained from the concentrated sediment.

Headache continued for several days, with dizziness and ringing in the ears. Repeated examinations of his urine gave an average of 71 ounces for twenty-four hours, of specific gravity 1012, every specimen containing a trace of albumen and a very few casts.

The normal urea discharge for this patient—adopting the usual estimate of 3½ grains per pound weight—was 679 grains daily, while his actual discharge was 420 grains.

I now made a diagnosis of contracted kidney, and in December, 1877, at my suggestion, he consulted Prof. Alonzo Clark, of New York, without, however, giving him my opinion.

Dr. Clark wrote me that he detected "slight hypertrophy of the heart, some albumen in his urine, and in one specimen hyaline casts;" and added, with that characteristic caution known to so many of us—that, "if this patient had not kidney disease, he was gravely threatened with it." Upon two or three urinary examinations Prof. Clark would seldom speak more strongly in a case of this kind.

The patient returned home, and I continued for a length of time my observations. The quantity of

* Centralblatt für prak. Augenheilkunde, January, 1879.

urine was always in excess; its specific gravity always low, with the merest trace of albumen and casts. There were the same nervous and dyspeptic symptoms above noted, but no dropsy, anemia, or vomiting. Again going to New York, this gentleman saw another physician of high standing, who pronounced his kidneys healthy, and his difficulty to be cerebral. In due time he came back to me in the same condition as before. He is still living, has gained in weight, has no dropsy, but suffers constantly from symptoms of moderate uræmic poisoning; and though thirty-two months have elapsed since I first saw him, I still consider his disease contracted kidney—sure to end fatally in time. Yet, to-day, the evidence of kidney disease would appear so slight to many physicians who should only examine a small quantity and a single specimen of his urine, that it would be rejected altogether.

A more remarkable case recently came under my notice, which is so instructive that I present it somewhat in detail.

I was consulted, Nov. 23, 1878, by a man of splendid physique, weighing 215 pounds. Previous to his present indisposition, he had never been sick a day in his life. He had always performed an immense amount of work, which he had been forced to abandon a few days prior to calling me, on account of rapidly developing debility, the cause of which was to him unaccountable. I could detect no organic disease, but immediately examined a specimen of his urine. It presented nothing abnormal, except that specific gravity was too low. Two or three days later attention was called to his excessive thirst, which led me to direct that all the urine passed in twenty-four hours be saved for examination. To my surprise the quantity amounted to 113 ounces; it was acid, of specific gravity 1001, without the slightest evidence of albumen or casts. From this date, Nov. 29th, until Dec. 31st, I accurately measured the urine every day, except Dec. 19th, and it was carefully examined for albumen and casts. The quantity varied from 64 ounces to 147 ounces, giving an average for twenty-two days of 104 ounces. The reaction was always acid, and the specific gravity fluctuated from 1004 to 1012.

Instead of the normal discharge of 752½ grains of urea daily, his average discharge was only 368 grains. There was no visual disturbance, and he did not suffer from headache, vomiting, or dropsy. The temperature was normal, but there was increasing debility, with great repugnance to food, and the condition of the urine as above stated.

Entire absence of albumen and casts for weeks, and my inability, on account of excess of fat, to determine that his heart was enlarged, led me, conjointly with other physicians, to deem the condition one of profound nervous disturbance, with undue nervous excitation of the kidneys; but, back of all, some centric, nervous lesion, probably of fatal import. I became dissatisfied, however, with this vague opinion, and determined to submit a report of the case to Professors Flint and Loomis, of New York. They were told what is here stated, examined carefully the record of urine and the discharge of urea, and did not hesitate to express it as their confident opinion that I was dealing with a case of contracted kidney, and would very early have an opportunity to verify their diagnosis.

In support of this belief, Professor Loomis adduced the results of six post-mortem examinations by himself, one of which was parallel to that now reported, in that albumen and casts were absent for a number of weeks.

Just at this time my patient, whose temperature had never been above normal, had an access of fever, with severe pain in region of right kidney, and retention of urine. I drew off 43½ ounces with the catheter, and now for the first time albumen was present, with epithelial and granular casts; in short, there were the symptoms and appearances of acute nephritis. Cystitis soon developed, and septicæmia followed, inducing a deepening coma, and death on the 31st of December. At the post-mortem examination, made Jan. 1st, the kidneys were found contracted, and in a state of chronic interstitial nephritis, with evidence of recent inflammation in right kidney.

The bladder was hypertrophied, and signs of recent cystitis were present. The middle lobe of the prostate gland was enlarged. The heart weighed 15½ ounces; other organs healthy.

We have here, gentlemen, evidence that a man had been able to do a large amount of work with the appearance of perfect health, while a most serious disease was in progress, for which he asked no advice until two months before it terminated his life. What I desire to have you specially observe is, that in this case the only symptoms noted were: rapidly developing debility, loss of appetite, extreme thirst, and the passage of urine excessive in quantity and of a low specific gravity.

Bartels, whose able article I hope all will read, in his report of seventy-seven cases of contracted kidney noted *but one* in which albumen was absent for any length of time. On page 440, Vol. XV. of Ziemssen, he reports one case in which albumen was entirely absent from the urine for twenty-nine days. *He therefore did not recognize the renal malady during life.* The urine of his patient was examined daily from the 29th of January to the 3d of March. An attack of fever occurred on the 27th of February, and slight albumen then appeared. The post-mortem revealed contracted kidneys. In my case the most careful examination did not afford a particle of albumen or any casts for twenty-three days, and I do not believe that they would then have appeared had not the acute inflammation supervened.

Why do I lay such stress upon these particulars?

It is to impress what is now firmly believed by myself, in the light of these cases, that the most serious of kidney lesions may be in progress, when, for over three weeks, neither albumen nor casts may demonstrate its presence.

How then is it to be recognized?

I believe that in the exact determination of the quantity of urine and urea passed daily we have an element for diagnosis more important than the profession has generally supposed.

Albumen may be absent, casts may be absent for weeks continuously, as I have shown; but when in any non-hysterical patient the urine is excessive, and the urea is habitually more or less deficient, and there is profound nervous and dyspeptic disturbance, and especially when we have with these conditions hypertrophy of the left ventricle of the heart, without valvular lesion to produce it, we are justified in the assumption of renal contraction as the cause—an assumption which time will probably develop into a conviction.

I need not add that contracted kidney is incurable, but its early recognition may often enable us to save our patients much useless medication, and so to disperse their daily lives as greatly to prolong them.

In the foregoing paper it has been my object:

1st. To call attention to renal cirrhosis as a distinct

affection, with hypertrophy of the left ventricle of the heart as a constant factor.

2d. To raise the question whether there is any such condition as fatal diabetes insipidus, independent of organic kidney disease?

3d. To impress the fact that, for the diagnosis of renal cirrhosis, long-continued examinations of the entire quantity of urine, voided in successive twenty-four hours, and estimates of its contained urea, are necessary.

4th. To prove by clinical experience that albumen and casts may be absent from urine for three weeks, when contracted kidney is far advanced, without headache, vomiting, dropsy, and uremic amaurosis.

Reports of Hospitals.

THE WOMAN'S HOSPITAL, PHILADELPHIA.

NOTES OF PRACTICE AND PECULIARITIES OF TREATMENT.

THE USE OF THE HOT-WATER DOUCHE IN POST-PARTUM HEMORRHAGE, WITH ILLUSTRATIVE CASES.

(Reported for the MEDICAL RECORD BY ANNA E. BROOMALL, M.D., Resident Physician.)

FOR many years the injection of cold water into the uterine cavity, as a means of arresting post-partum hemorrhage, has received varied consideration. The older obstetricians considered it a bold procedure, attended by many dangers, and not to be resorted to except in extreme cases. Some thought it impracticable from the difficulty of obtaining the necessary implements. Others disapproved of it, because its employment necessitated wetting the patient's bed and clothing; the latter objection, even if it could not be met by the use of a bed-pan, should not weigh for a moment when life is in danger.

The only point worthy of consideration in the practice is its hæmostatic value. In regard to this, we do not find that it has met with the success which was claimed for it, for which perhaps some allowance should be made from the want of confidence in it, and hence want of thoroughness in its use; however, in the instances in which it was resorted to in the Woman's Hospital, it failed to arrest the hemorrhage, notwithstanding all due care was taken in its employment, ice-water was used, and the stream was directed into the uterine cavity. For the past two years it has been altogether abandoned, and the hot-water vaginal douche substituted.

It is remarkable that so valuable a method of inducing uterine contractions as the stream of hot water should not have been utilized earlier in the treatment of post-partum hemorrhage. Kiwisch, in 1846, recommended, as a means of inducing premature labor, a continuous stream of warm water to be directed upon the cervix uteri.

Scanzoni directed further, for the efficiency of the douche, that the temperature of the water should be from 100° to 110° Fahr., the stream should be continued from ten to fifteen minutes, and should be repeated every two or three hours, until the onset of uterine contractions. Churchill found that the separation of the membranes from the uterus, together with the heat from the water, brought on labor after eight or ten repetitions.

The credit is said to be due to Dr. Emmet, of New York, for the use of the hot-water vaginal douche for the arrest of hemorrhage in gynecological practice; but little has been said or written upon the value of this treatment in post-partum hemorrhage, with the exception of its recommendation in the second edition of Playfair's System of Midwifery, and of a report by Dr. Atthill of its successful use in sixteen cases in the Rotunda Hospital, of Dublin. A remedy so efficient, always available, and so free of danger, should be taught from every chair of obstetrics and in every work on midwifery.

There is no anxiety in the entire obstetric practice greater than that attendant upon the occurrence of post-partum hemorrhage. If ever prompt and efficient aid can turn the balance for life or death, it is at this moment. I can compare the sensations of the accoucheur at such a time to nothing more agonizing than the feelings attendant upon efforts to save the drowning, when at every grasp the unfortunate slips further and further away, slipping into death from between the very hands extended to save.

I have had the misfortune to lose two patients from post-partum hemorrhage, being called in both instances after delivery. Friction on the abdomen, pressure of the uterus, elevation of the hips, clearing the uterine cavity and vagina of coagula, and use of ergot, all failed in one case to induce uterine contractions, and the patient died within one hour after delivery. In the other instance the uterus contracted, but too late to save life. Since I have found that hot-water vaginal injections will produce such prompt results, I feel that had I then known their use my patients might have been saved. To those obstetricians who have had a similar experience, I have no need to urge the adoption of any means which has proved efficient in the arrest of hemorrhage; but it is to those beginning the practice of obstetrics, and to older practitioners, who thus far have fortunately escaped these frightful obstetric accidents, that I would urge the trial of a means, always available, since the necessary implements are to be found in every household, and always efficient, as I believe, since it never yet has failed me.

The means of controlling hemorrhage from the uterus after delivery, is by thrombosis of the uterine sinuses, and this may be brought about in two ways—by uterine contractions, and by the direct application of styptics, with this difference, however, that in the former method the contracting muscles limit the clots to the orifices of the uterine sinuses, while in the latter method there is nothing to limit the thrombi, and consequently the patient is subjected to the great danger attendant upon the washing of clots into the general circulation. Thus it is found that the safer treatment in post-partum hemorrhage is to employ some means which will imitate nature by exciting uterine contractions, and for this the hot-water douche proves efficient. It is thus employed: A bed-pan, largest size, is placed beneath the patient's hips. A Davidson's syringe is used in preference to a fountain syringe, as an intermittent stream has been found more effectual in exciting contractions than a continuous stream. The water should be of the temperature of 110° Fahr., and not less in quantity than two quarts. A higher temperature is not well tolerated, and a lower temperature is ineffective. The amount of the injection is given as not less than half a gallon, but the rule is to continue the injection until the return stream is clear. Care is taken to see that the syringe is in good order, and that the air is thoroughly forced out before use. According to Dr. Anna

M. McAllister's suggestion, we have substituted for the ordinary vaginal nozzle a tube of the same calibre, but six inches in length, which has the advantage of easy insertion, and obviates partly the great objection to the use of syringes in hospital practice, namely, the contact of the soft rubber with the vaginal walls. I am convinced that septic materials have been absorbed by the hose of the syringe and carried from one patient to another. I believe the only safety is in the provision of a separate syringe for each patient, to be used for her alone, and to be destroyed upon her discharge. The pecuniary objections to this in hospital practice are insurmountable, so we make a compromise between money and puerperal infectious diseases, by using the long metallic tube in place of the shorter vaginal nozzle. The tube should be inserted within the uterine cavity through the internal os, which may be recognized on careful examination, and it should be introduced to the fundus. It has been suggested to enlarge the perforation at the extremity of the tube in order to obtain a larger stream of water. Any coagulum which may interfere in the introduction of the nozzle, should be broken up, and the clots will be carried out in the return stream. If the right hand is used for introducing the tube, the left hand should be placed upon the abdomen, and should grasp the fundus, which should be the rule in any case where there is necessity to carry hand or instrument into the uterine cavity. As the water is injected, the relaxed uterus will become firm and hard beneath the hand, and the stream from the vagina will be less and less mixed with blood. It should be observed that in this simple operation we combine other means, and very important means, for exciting uterine contractions and arresting hemorrhage, namely, first, clearing the vagina and uterine cavity of coagula, and second, manual compression of the uterus. Nor does it interfere with other valuable expedients in post-partum hemorrhage, as elevation of the hips, etc. The rule for the time of continuance of the douche, as well as the frequency of repetition, depends not only on the promptness of the establishment of uterine contractions, but also on their permanence.

In the lying-in wards of the Woman's Hospital during the past six months, it has been the routine practice to use the hot-water vaginal injection in every case after delivery of the placenta, and, during that period, notwithstanding circumstances predisposing to relaxation of the uterus, there have been but two cases of post-partum hemorrhage, neither of which were from uterine relaxation, but both from laceration of the cervix. In several instances prolonged and complete anesthesia was necessary for obstetric operations; but the uterus contracted promptly after the use of the douche, and in the instances of hemorrhage the flow of blood was quickly arrested.

These two cases, to which reference has been made, with one occurring in the out-practice of the hospital, are of sufficient interest to warrant their report in detail.

CASE I.—Elizabeth McL., aged 30, Irish, primipara, employed as a domestic, was in labor when admitted September 13, 1878. Dilatation was slow, and upon its completion, pains being inefficient, and the head having reached the inferior strait, the patient was etherized, and I applied Simpson's forceps and extracted a living child nine pounds in weight. Six minutes after the birth of the child, the placenta was easily delivered according to Credé's method, and, while the patient was still unconscious from the anæsthetic, the uterus being firmly contracted, a large

stream of bright blood was observed to flow from the vagina.

The hand was introduced, and the vagina and uterine cavity found free of coagula; but upon further investigation the blood was found to flow from a deep laceration on the left side of the os uteri. The wound extended up into the uterus, but was limited to its inner surface, thus avoiding an opening into the peritoneal cavity. The os uteri was drawn down to the vulvar orifice, where bleeding could be watched, and, from the force of the flow as well as from the size of the stream, it was believed that the circular artery was opened. It was decided before resorting to the difficult operation of ligation to try the hot-water douche. The grasp upon the os was relaxed, a stream of hot water directed upon the wound, and the flow of blood was immediately arrested. The patient made a good recovery, and was discharged seventeen days after confinement.

CASE II.—Lizzie B., aged seventeen, American, primipara, was admitted in October, 1878. Labor began on the evening of the 18th; dilatation was, however, not complete until the afternoon of the following day, when the uterine contractions were so feeble that at 4.23 A.M. I applied Simpson's forceps, and in twelve minutes extracted a living child of 9½ pounds weight. There was no delay in the delivery of the placenta, and there was no hemorrhage either after the birth of the child or after the expulsion of the placenta. The lying-in was normal, with the exception of slow involution of the uterus, but there was no pain, tenderness, or other symptom of metritis. Suddenly on the seventh day, during my absence from the hospital, the patient being still confined to her bed, there occurred a hemorrhage from the vagina; the flow was profuse, but was temporarily checked by elevation of the hips. After an interval of two hours the hemorrhage was repeated, and was severe, attended with great pallor, faintness, and cold sweat. I then made a careful vaginal examination, and found a deep rent on the right side of the cervix, and extending into the vagina. I traced the flow of blood to the wound. Immediate resort was had to the hot-water douche, which completely controlled the hemorrhage for the time. The flow of blood returning, though with less force, a continuous stream of hot water, by means of a reservoir syringe, was maintained for two hours, and there was no further hemorrhage. The patient was very anæmic, and made so slow a recovery that she did not leave the hospital until the fifty-fourth day after parturition. Previous to her discharge vaginal examination revealed a deep laceration on the right side of the cervix. The edges of the wound were gaping, and cicatrization was not entirely complete. Bands of adhesion extended down to the right lateral wall of the vagina. This case is certainly unique. A secondary postpartum hemorrhage, which must have been caused by a slough of the cervix opening the circular artery. The amount of blood could have come from no other source, as a vaginal examination at the time of the hemorrhage showed that the flow did not come from within the uterus, thus excluding the placental site as the source of the hemorrhage.

The third case occurred in the out-practice of the hospital. Jette S., aged twenty-two, German, already the mother of two children, was delivered by a midwife on January 30, 1879. The pains were said to have begun at three o'clock in the morning, but the labor was not terminated until 9.30 A.M. of the same day. The child was large, the pains were reported to have been severe, and the labor rapid. Interference

in the placental delivery was positively denied. At about ten A.M. the midwife recognized "something wrong," and sent for medical aid.

Dr. Frances E. White was summoned at noon, and found complete inversion of the uterus, the patient in collapse, pulse 140 per minute, and very feeble. Dr. White sent for me to assist her, but I did not reach the patient, who resided some distance from the hospital, until one P.M. I found much the same condition as reported on Dr. White's arrival. The patient was very restless, and was making bearing-down efforts at short intervals. Vaginal examination revealed a round body, size of a child's head, projecting into the vagina. The upper constricted portion, if any part could be called constricted, was found to be the rim of the os, and continuous with the tumor. The surface was covered with a film of coagulated blood, and there was a slight oozing upon an attempt to reduce the inversion. Anæsthesia was then determined upon, and, as ether was being procured, Dr. Edward T. Watson came, who had been summoned by the family previous to the arrival of Dr. White, and who very kindly assisted in the case. Etherization being effected, I introduced the right hand into the vagina, and by making upward pressure on the most dependent portion of the tumor, first with one finger and then with two, I succeeded in indenting the uterus, and by careful and continued pressure in correcting entirely the inversion. The uterus, when replaced, was completely relaxed, giving the hand the sensation of being in a great rubber bag, and all efforts at friction over the abdomen, movement of the hand within the uterine cavity, etc., failed to excite contractions. A hypodermic injection of ergot was equally unsuccessful. Resort was then had to the hot-water douche, and immediately firm and strong uterine contractions followed its use, the hand was withdrawn, and the uterus remained firmly contracted. There was no flow of blood after the reduction—in fact, there had been no very great hemorrhage since Dr. White's attendance; but from the previous flow the bed and clothing of the patient were saturated, and a vessel half filled with coagula stood beneath the bed. During the etherization the pulse improved in volume and diminished in frequency, but upon recovery of consciousness the radial pulse could not be counted, and the patient had all the symptoms of extreme collapse. The restlessness attendant upon hemorrhage was anticipated by the hypodermic use of morphia. The patient, being warmed and stimulated, rallied somewhat, so that the radial pulse returned, and beat at the rate of 130 per minute, and a slight trace of color appeared in the lips. This improvement, however, was but temporary, and at seven P.M. the patient became very restless, notwithstanding repeated hypodermic injections of morphia. She complained of intolerable thirst, her respiration became sighing, the skin lost its warmth, and the radial pulse rose to 170 per minute. Dr. Albert H. Smith, who very kindly saw the patient with us in the evening, agreed that transfusion of blood was the only hope. Dr. Charles T. Hunter very promptly and cheerfully consented to perform the operation, which, however, owing to unavoidable delay, was not begun until ten P.M. When about an ounce of blood had been injected the patient became moribund, and died during the transfusion.

The examination of the placenta showed it to be entire in its outline; it was somewhat torn about the centre, but there was little or no loss of its substance.

The hot-water douche acted most promptly and efficiently in this case, exciting uterine contractions,

in actual collapse, and not only inducing contractions but maintaining them, for even after death the uterine globe was found firm and contracted below the umbilicus. Had assistance reached the patient earlier after the occurrence of the accident, the inverted uterus been replaced, and contractions excited by the stream of hot water, I believe the result would have been very different.

Progress of Medical Science.

DIABETES COMPLICATED BY SYMMETRICAL GANGRENE OF THE PLANTAR REGIONS.—Dr. Magnin published in the *Journal de Médecine* the following case: The patient, aged sixty-four, had always enjoyed good health up to 1871; then he began to suffer from diabetes, the urine containing fifty-four grammes of sugar per litre. He was treated for this with some success, but in March, 1878, there was still some sugar present in the urine. At this time the patient was much alarmed at the appearance of symmetrical rows of purplish spots, the size of peas, on both feet, especially the right one. This eruption was very tender, and gave great pain not only on walking, but also while resting. The pains on lying down were described as of a lancinating character, similar to an electric shock, equally rapid in their appearance and disappearance. Diabetic gangrene was suspected, and local applications of quinine and arsenic, together with the internal administration of quinine, were made use of. The symptoms, however, grew worse, and the affection progressed rapidly, the skin on the right foot having a macerated appearance. As a last expedient, Dr. Magnin resolved to try local oxygen-baths, without, however, placing much faith in them. They were administered by drawing over the leg and foot a rubber tube, into which the oxygen was conducted. The patient took a bath of half an hour the first day without experiencing any relief. The foot was very red, and perspired abundantly. The treatment was continued for twelve days, after which time all traces of the purplish spots and the pain had entirely disappeared. The patient still suffers from diabetes, but is comparatively healthy and able to attend to his business.—*The London Medical Record*, March 15, 1879.

IDIOPATHIC GANGRENOUS CELLULITIS ABOUT THE RECTUM.—In a clinical lecture delivered in Queen's College, Birmingham, Furneaux Jordan, F.R.C.S., describes a gangrenous affection of the cellular tissue about the rectum of which he has seen several cases. They have all occurred in big, heavy, middle-aged men—men of continual activity and excitable temperament, always walking or travelling, or eating or drinking; in men who combined two bad habits—eating too much and drinking too much; in men sufficiently well-to-do to indulge at will, and who firmly believed that excess of work needed excess of food and liquor; in men who were indifferent to weather, and had been notably exposed to cold and wet. The pale, hard, slightly lobed, extremely prominent swelling projecting between the big buttocks of a big man is not easy to describe. It may begin anywhere in the vicinity of the rectum, around the tube or near the surface; if it begin deeply, it soon comes to the surface; if it begin under the skin, it soon extends deeply. Its deep position is sometimes known by the effects of pressure, as on the sacral plexus. Fever and extreme prostration are present. The progress of

the disease is very rapid. The skin over the swelling, if not cut by the surgeon, quickly melts away, and discloses a mass of dead, black, fœtid tissue, but, as a rule, no suppuration. The slough comes away rather slowly; a cavity, usually of extreme size, is left, which closes tardily, and leaves, curiously, no fistula, as does the ischio-rectal abscess. The gravest feature in the progress of these cases is the great tendency to relapse or extension, or both. Cellulitis, closely followed by gangrene, may suddenly extend, in possibly fatal, and always dangerous, directions. Early and active counter-irritation, and prompt incision of the swelling are recommended.—*The British Medical Journal*, January 18, 1879.

THE PATHOLOGICAL CONDITIONS OF ALBUMINURIA.—Rumberg has summed up the results of his observations as follows: The transudation of albumen into the urine always takes place in the Malpighian bodies, and is due to an increased permeability of the walls of the convoluted tubes and their epithelial lining. The particles of albumen which are suspended in the blood-serum, and which, under normal conditions, cannot transude through the membranes of the Malpighian bodies, are washed through them, together with the other constituents of the urine, and mix with the latter.

In a healthy kidney this increased permeability is due to a considerable decrease in the difference between the blood-pressure within the Malpighian bodies and the counter-pressure within the urinary tubuli. Here, therefore, the albuminuria would only be accidental or transitory, and may, according to what has been said, be ascribed either to a considerable increase in the pressure in the urinary tubules, or a decrease in the blood-pressure in the Malpighian bodies, or to both causes combined. If the albuminuria should, however, persist, then the increased permeability of the membranes must be ascribed to some degenerative or suppurative change within the convoluted tubes of the Malpighian bodies; here, too, pressure has a marked influence on the permeability of the lining, and consequently on the amount of albumen contained in the urine, in the same way as has been quoted above. Certain kinds of the albuminous bodies, such as egg-albumen and hæmoglobin, are transuded much more easily than serum albumen. If, therefore, these substances have been mixed in some way with the blood-serum, they immediately transude into the urine like dissolving salts, even if the blood-pressure should be normal and the kidneys healthy.—*The London Medical Record*, March 15th.

TRICHINOUS PORK.—H. F. Atwood and W. F. Belfield, M.D., of Chicago, have been making some researches on this subject at the request of the Health Commissioner of that city. One hundred hogs were examined, and of these eight were found infected with varying degrees of intensity. A rat fed on this meat enjoyed the best of health, but, when killed, every muscle was found affected; from this it was deduced that trichinous animals are not generally out of health. Salting and smoking do not destroy the parasite, but sulphurous acid does. This acid readily permeates the entire ham, and is as readily expelled, and, owing to its cheapness, the addition of a sufficient quantity of it to the pickle would add but a trifle to the expense. The injection of a limited number of trichine is not followed by unpleasant results, as was proved by Dr. Belfield, who ate a portion of the rat referred to, which was demonstrated, under the microscope, to contain twelve living worms. Twenty-six days later no unusual symptoms had re-

sulted. The only infallible means by which meat inspectors can detect the parasite in a carcass of meat is thought to be the microscope. The animal is destroyed by a temperature below that of boiling water.—*The Physician and Surgeon*, March, 1879.

THE TREATMENT OF RUPTURED BLADDER.—Mr. Heath narrated to the Royal Medical and Chirurgical Society a case from his own practice, in which rupture of the bladder was diagnosed principally from the tense condition of the abdomen, from the fact that a catheter, on entering the bladder, drew off clear urine, but, on passing further, gave exit to bloody urine, which ebbed and flowed as the patient breathed, and that warm water, injected through the catheter, failed to distend the bladder, and was felt in the groins and abdomen by the patient. The abdomen was opened, and the rent in the bladder closed with a continuous catgut suture. A catheter was tied in, and gave exit to clear urine till the fifth day, when it became bloody, and symptoms of peritonitis developed, the patient dying just six days after the accident. At the post-mortem examination the lower portion of the bladder-wound was found open. Mr. Heath recommended in future cases a trial of catheterism and washing out of the peritoneum as practised by Dr. Thorp, reserving lateral lithotomy for cases in which the rent in the bladder could not be reached with the catheter. Mr. Bryant agreed with Mr. Heath, with regard to the operation of laparotomy, but thought that cystotomy through the perineum, as in lateral lithotomy, should be performed in all cases. Messrs. Marsh, Willett and Holmes were encouraged by the results of the operation of laparotomy, and urged that it should be tested further. The two cases in which it had been tried owed their failure to the giving way of the sutures in the bladder, and could not be quoted against the probable efficacy of the operation. It certainly seemed impossible to Mr. Marsh that clots could be emptied from the peritoneum by washing out the cavity through the bladder, and the importance of completely cleansing the cavity was recognized by every ovariotomist. The mere operation of opening the abdomen would, he was sure, come to be regarded as less and less dangerous. Great importance, however, attached to free drainage.—*The Lancet*, March 1, 1879.

ALBUMINURIA TREATED BY THE INHALATION OF OXYGEN.—At a meeting, January 8th, of the Société de Thérapentique, M. Dujardin-Beaumetz read a paper on a case of albuminuria in which the albumen had entirely and rapidly disappeared after some inhalations of oxygen. The patient had reached the last stage of the disease; every diuretic had been employed, but without success, when inhalations of oxygen were resorted to. The albumen disappeared within the next twenty-four hours, and had not reappeared since. Twelve days had elapsed, and the author wished to know if similar cases had been observed before, and if his treatment might be considered as attended by permanent success. In the discussion which followed it was remarked that similar cases had been observed, but the effect of a cure had never been permanent, the albumen generally appearing after two or more months.—*The London Medical Record*, March 15th.

"DRYING-UP" THE MILK.—At a meeting of the New York Academy of Medicine nearly all the speakers agreed that the best plan for "drying up" the milk in non-nursing mothers is to let the breasts *entirely alone*; no pumps, ointments, belladonna, or friction, etc.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, May 3, 1879.

COMPARATIVE PATHOLOGY.

THERE seems to be little doubt that the investigations of diseases are now to be turned in a new direction, and one that has as yet received little attention from modern pathologists. It was not very long ago that we were all carried away by the brilliant studies and apparently conclusive arguments of Liebermeister, who told us that typhoid fever was produced by foul drinking water, and the emanations from sewers and privies. Later English investigations pointed toward milk as the vehicle of the poison, and so to the water used by the milk dealers, which was supposed to have been infected by typhoid excrementitious matters. Still later, milk seemed to have diffused the disease which coincided very remarkably in its area with the distribution of the supply from a particular dealer. This milk, upon close examination, appears to have been uncontaminated with any foreign matter whatsoever, and the question consequently arose, may not the poison have been derived from the cow herself?

Some observers have thought that they could trace scarlatina in a somewhat similar way through milk. In a recent discussion before the Pathological Society of London, the relation between the mammitis or mastitis of cows, known as "garget" or "caked bag," and diphtheria in mankind, was earnestly discussed. Whether or not a causal relation may ever be traced, it seems to be clear that these matters deserve to be looked into by those who are concerned with the investigations of disease, and then there will be no occasion for the criticism launched by the distinguished veterinarian, George Fleming, that "if physicians and surgeons will discuss the diseases of animals, especially in relation to the public health, they should possess some knowledge of these diseases." We must remember that the discovery of the nature of cow-pox, and its capacity for being inoculated in the human subject, has been the means of saving

thousands and thousands of lives, and preventing the occurrence of those unsightly blemishes that small-pox leaves. The foot and mouth disease of animals has some important relations to mankind, for it is communicable by milk and produces ulcerations of the mucous membrane and disorders of the intestinal tract. The carbuncular or anthracoid diseases of animals, have also been objects of special interest through the studies of Bouley, Chauveau, Colin, and others, and their relation to malignant pustule in the human species has led to frequent and extended inquiries into the nature of the poisonous element. Indeed, the microphytic germ theory of disease derives much of its strength from the vegetable elements that are alleged to carry the poison of these affections. It is well known that the domestic animals have much the same diseases as man. To enumerate those of a single species, the horse has our ordinary lung and heart diseases, with but comparatively slight differences. He has also various forms of Bright's disease, pyelitis, diabetes, and in nervous affections, cerebro-spinal meningitis, epilepsy, chorea, etc. Besides these he has glanders, charbon, and the like, which are apt to be fatal when communicated to mankind, and should, therefore, be thoroughly understood by human physicians. There are other practical considerations, however, which should lead pathologists to make a study of disease in animals.

Precise notions as to the essential nature of the pleuro-pneumonia of cattle would be of great pecuniary value to the country at large, and might lead to the enactment of such provisions in the different States that the disease would be thoroughly exterminated with the least possible outlay of money. At present it is very desirable to do the work effectively, and it is accomplished by the slaughter of all infected cattle, indemnity of some kind being made to owners. Whether or not this is the cheapest and most effectual plan, for that is the plain issue in this case, is a matter under discussion. At the same time it may be said that, according to the Second Annual Report on Infectious Animal Diseases in Prussia, for the year ending March 31, 1878, the favorable decrease in the extension of this disease finds its explanation in the more exact execution of the law requiring the slaughter of all diseased animals.

But there are other epidemics among animals, notably the swine plague or hog-cholera, whatever its real nature may be. This disease is said, by good authority, to be the most fatal disease that exists among hogs. So important a position has it assumed that the veterinary department of the Privy Council in England has taken special measures to control it. These matters relate to the general sanitary affairs of the country, and we recommend them to the early attention of our National Board of Health, together with the subject of trichinosis, which, according to our continental brothers, exists without much let or hinderance in this

country, and necessarily occasions much annual loss of life. This also brings up another point, which for the student of human pathology is of immense interest. It is the general subject of parasites which have so largely their habitat in animals, and are thence often transferred to mankind. Recent observations seem to point toward important discoveries in this direction. It is a broad field and has as yet yielded no fruits commensurate with its extent. But there is a broader one still and one that is even less known. It is the general comparative pathological anatomy of animals. Much of error that has crept into the conclusions from experiments on animals may be traced to an imperfect knowledge of their ordinary diseases. This applies especially to investigations on the nature of tubercle. Then it is hardly conceivable but that a study of Bright's disease, diabetes in animals, and other affections of vast importance to the human family, should unveil some points of great value in elucidating obscure points in the disease. It is in this way that comparative anatomy has ministered to human anatomy. As the one is higher than the other because it presupposes a knowledge of it, so is comparative pathology the highest of all, as it requires a knowledge of the anatomy of men and animals both in health and disease. John Hunter recognized these bearings, but since his time it would appear that no British student of human medicine has entered the field, and certainly, within our knowledge, no one in this country has made these matters a study. In France, however, according to Fleming, Bouley, Le Blanc, and Colin, take their places as comparative pathologists in the Paris Academy of Medicine. Veterinary science is indeed an attachment to human medicine, and is capable of giving it great and practical assistance. We are, therefore, glad to see that the distinguished Chauveau, of Lyons, director of the veterinary school there, has accepted a chair of comparative pathology at the new university of that city, and more recently, that the University of Pennsylvania, always among the foremost in the cause of medical education, has made a move in the same direction.

MOISTURE AS AN IMPURITY IN AIR.

ABOUT three years ago Dr. T. J. Turner of the U. S. Navy, who was then serving on the *Tennessee*, had some trouble which we referred to at the time, with the commanding officer in regard to the hygienic regulations of the ship. Dr. Turner insisted that the constant wetting and holystoning of the berth-deck was injurious to the health of the sailors and was interfering with the recovery of some of his patients. The commander considered the doctor's suggestions presumptuous and ordered the wetting process to go on. Protestations were made, not only in vain, however, but with the result, finally, of stopping altogether the scientific investigations into the quality of the air on ship-board, while Dr. Turner was referred to head-

quarters on account of his obstinate and unwarrantable interference in the management of the ship's affairs. These events developed into much prominence the stupidity and arrogance which appear to have been the salient traits in the character of the commander. However, after a good many further troubles, Dr. Turner was enabled to continue his investigations, and the results of them have been recently published by the Medical and Surgical Bureau of the Navy Department. The work is entitled "Air and Moisture on Shipboard," and it contains some facts of much interest to landsmen as well as sailors. Some of his principal points deserve summarizing:

I. Four out of 10,000 volumes of the atmosphere is the normal amount of carbonic-acid, and six parts in 10,000 is the limit of impurity that is regarded as safe. This carbonic acid is generally considered a measure of the other impurities in respired air, and especially of organic matter. When the amount of CO₂ reaches seven parts per 10,000, the air acquires a disagreeable odor. In unrespired air, the CO₂ may amount to ten parts per 10,000 without injury, which indicates the prominent part played by the other impurities.

II. Fifty cubic feet of still air are in one minute defiled by one man. This would be very alarming did we not remember that still air is a very rare thing for landsmen to find. Upon half a dozen government vessels, however, which are mentioned, this limit is said to be reached in less than one and a half minutes, and on berth-decks of vessels in commission the air always has carbonic acid in abnormal excess. Thus, on the *Powhatan*, during three months at Norfolk and New York, the CO₂ ranged from 11.8 to 19.6 per 10,000.

III. Moisture increases the amount of CO₂ in the air; it diminishes the exhalation of aqueous vapor from the skin and lungs, limits excretion, and, in consequence, life cannot be prolonged in air saturated with moisture at a temperature of 90° to 100°. In fact, humidity is the most dangerous air agent.

IV. Air should be considered dry or moist in proportion to its removal from saturation. Taking the point of saturation as 100, the average degree of saturation is from 50 to 70, varying with the temperature, the capacity for moisture being doubled for every 27° F. rise.

V. The continual washing and holystoning of the decks add very much to the natural humidity, and consequently to the unhealthiness of the sailors' quarters. To corroborate this, Dr. Turner gives a large number of statistics, showing that ships which have been kept dry have had far less sickness than those in which much wet scrubbing has been done. He recommends, therefore, that all decks below the spar-deck should be lacquered, and should be kept clean with the help of as little water as possible.

The value of Dr. Turner's observations and conclusions lies especially in the prominence which he gives

to moisture as an impurity in air. Although not alone or first in showing the bad effects of this condition, yet he has worked the matter up more exclusively, and brought it forward with more emphasis than is usually done in works on hygiene. If his conclusion is correct in regard to its absolutely fatal influence at a temperature of 90° to 100°, the fact may well be borne in mind, both in general questions of hygiene and in applying the now popular method of keeping patients with croup, etc., in a cloud of steam for considerable periods of time.

In regard to moisture on shipboard we are inclined to think that the doctor lays too much stress upon its special importance. Certainly his statistics are not sufficient to demonstrate the uniform and inevitable noxiousness of aqueous vapor. Many long voyages have occurred in which there was plenty of wet scrubbing, and no great amount of sickness. He has proved, however, that moisture is an agent which may do much harm, and poor Jack should be given the benefit of whatever increased healthfulness a drier berth-deck will afford him.

CREMATION SOCIETIES.

Following upon the popularity of cremation in Holland, and the governmental approval of it in Switzerland and other places, efforts are making in London to have a cremation society incorporated there. These attempts have called out some adverse criticisms from *The Lancet*. That journal appears to be considerably alarmed at the possible introduction of the new mortuary ceremony and it ends a fine antithesis with the appalling, though somewhat redundant announcement that "cremation will destroy the safeguards of public security." It would certainly be very unpleasant to have the "safeguards of our security" taken from us, but we hope the imminent peril is a little exaggerated. The means in which cremation will thus impair and perhaps entirely incinerate the foundations of society is this: the bodies of those who have been poisoned, or have died a violent death, being entirely destroyed, there will be lost with them strong evidences perhaps against the criminal parties. With the opportunity therefore of thus forever hiding in the flames of a reverberatory furnace the witness of their guilt, murder is expected to stalk abroad and the red right hand of Rapine flourish uncontrolled.

Now this danger has been considered by the authorities which have already incorporated cremation societies. That at Zurich, for instance, is obliged "to have the body carefully examined by the district physician and to have an autopsy made as a rule, in order to exclude the possibility of violent death." Regulations of this kind will reduce the danger of unappeased justice to a minimum, or exclude it altogether. For, be it remembered, the argument now concerns only the incorporation of a society. The

general introduction of cremation is at present entirely impracticable and need not be discussed.

But *The Lancet* further argues against cremation on the ground that the asserted dangers to wells, etc., from country and suburban churchyards are not very great and can be more easily avoided in other ways than by cremation. The way suggested is to have the wells dug deeper, and it is asserted that the people could have good water if they would only take the trouble to thus deepen their sources of supply. Such a plan does not offer a practical remedy in this country at least. The depth of country wells here is from fifteen to twenty feet; if they were sunk a hundred feet deeper we doubt if the percolations of a graveyard would be any more sweet. There are few towns where Artesian wells can be dug.

While thus criticizing these arguments against cremation we do not assert that it, at present, should be the general mode of disposing of the dead. It is an undoubted fact, however, that to burn the body is the best way to treat it, from a sanitary point of view, and it is a process that need not offend either the religious or the aesthetic sense. Furthermore, it must be admitted that in the present burial system there is a positive danger to the health of the community, and there may be also, we are obliged to add, injury to the feelings of the friends through the now popular occupation of body-snatching. Thus, though cremation may not be a necessity at present, we may be forced to it as communities become more and more overcrowded. And if there are persons who wish to have themselves incinerated, the authorities should by all means allow them to have it done. Certainly no one need be alarmed by the phantoms that are afflicting the imagination of our English brethren.

Reports of Societies.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, April 7, 1879.

DR. J. C. SHAW, PRESIDENT, IN THE CHAIR.

NEURITIS ASCENDENS, WITH SECONDARY CHANGES IN THE SPINAL CORD.

DR. V. P. GINNEY reported a case of neuritis ascendens, with secondary changes in the cord, occurring in a man *et. 35* years. His family history was unimportant. He was married; was the father of healthy children; had never had syphilis; and his habits were good. During the war of the Rebellion he contracted dysentery, which had recurred at intervals of a few months ever since. The patient was anemic and somewhat emaciated, when a boil appeared in the region of the olecranon. A second boil appeared upon the posterior part of the elbow. A month later a feeling of numbness was developed, affecting the entire posterior surface of the forearm, and there was notable anaesthesia in the line of the ulnar nerve. A detailed account was given of the clinical history of the case, accom-

panied by remarks regarding its bearing upon the question of reflex paralysis, neuritis migrans, and neuritis ascendens. The case was regarded as one in which the internal and the external cutaneous and other nerves were primarily affected by extensive inflammation from a boil upon the elbow. The musculo-spiral, the brachial and the occipitalis minor nerves became involved. Dr. Gibney believed the case demonstrated that ascending neuritis was capable of developing secondary inflammatory changes in the cord by means of simple extension of the process *per continuitatem*.

DR. E. C. SEGUIN remarked that the subject of ascending neuritis had received but little attention, and for that reason the case reported by Dr. Gibney was an important one, although the positive demonstration of changes in the spinal cord was wanting. He then referred to a case which Dr. Weber, of Boston, had placed upon record, in which the demonstration was complete, as microscopical examination of the spinal cord had shown. He also referred to a case of his own in which the brachial plexus was removed by operation for the relief of pain incident to the development of neuromata, secondary to amputation of the arm. In the portion near the scapular muscles there were evidences of chronic hyperplastic neuritis, and in the other portions evidences of Wallerian degeneration. It had also been demonstrated by Dr. Gull that in cases of numbness and paraplegia following vesical disease the lesion did not follow the nerves, but that the myelitis was produced through phlebitis.

APHASIA DUE TO THROMBOSIS OF SMALL TWIGS SUPPLYING THE SPEECH REGION.

DR. PUTNAM-JACOBI presented a patient with the following history. A remarkably healthy-looking boy, four or five years old, who had not had any sickness during his life, began to exhibit, in the latter part of February, some change in his mental condition. He first began to say curious phrases, soon began to run about in a wild manner, gradually spoke less and less, and at the end of a week ceased to say anything. With the loss of speech there was soon loss of power to make signs or gestures. He amused himself quietly alone. He did not cry aloud. There was no fever, vomiting, or convulsions. His hearing seemed perfectly good, as well as his other special senses. He did not seem to recognize the meaning of words, yet gave a nod of acceptance when certain articles were exhibited, as an apple, or a piece of cake, while he made no expression whatever when certain other articles, such as money, were shown, although previously he had been very fond of handling coins.

The temperature of his head was as follows:

Left frontal region, 95° F.; right, 94° F.

Left parietal region, 93½° F.; right, 94½° F.

Left occipital region, 96° F.; right, 93½° F.

Left vertical region, 92½° F.; right, 93½° F.

The temperature of the mouth was normal.

A diagnosis of aphasia due to thrombosis of small twigs supplying the speech region was made, and the patient was put upon iodide of potassium, in five-grain doses, three times a day. He first came under the doctor's observation March 7th. On March 12th he spoke for the first time, and said, "Stop that." A few days after he again ran about in a very wild manner. On the 20th of March he spoke several words, and at about the same time had an attack of crying. On the 27th of March he sang a little, and on the 28th he seemed to understand something said to him, and since that date his condition had remained nearly unchanged.

DR. E. C. SPITZKA remarked that the patient was one whom he had seen a little time before he came under the observation of Dr. Jacobi, and at that time the child was cachectic, there had been classical strabismus, a febrile movement in the evening, and distinct hallucinations of sight. He had entered the case upon the books as a mild one of *tubercular meningitis*. He could hardly understand how a gradual occlusion of small vessels in the speech region could occur except by tubercular process, as he thought it could be safely said that no other specific taint was present.

DR. JACOBI remarked that she had been unable to obtain any history of febrile movement, and the absence of fever was one reason why she had excluded meningitis.

DR. SPITZKA had therefore elicited symptoms which she had been unable to obtain.

DR. E. C. SEGUIN remarked that in the absence of grave symptoms—such as hemiplegia, tendency to coma, and the more serious results of occlusion of blood-vessels in the brain—he was not quite prepared to accept the diagnosis made by Dr. Jacobi. He further referred to a case which in some respects was similar to the one presented, namely, one in which there were alternations of violent mania and melancholia. During the melancholic periods the child was absolutely mute.

DR. HAMMOND remarked that a similar case came under his observation some six or eight years ago, in which there was no indication whatever of paralysis. The aphasia was of about the same character as in the case presented. He regarded it as a functional affection. All efforts to cure the child proved ineffectual. Believing it to be reflex in character, he resolved to make an experiment, and treated the patient for worms. A large number of worms were expelled, and as soon as gotten rid of the child was well. He regarded the present case as functional in character, and thought the child would ultimately entirely recover.

DR. JACOBI remarked that in her case the mutism coincided with the periods of excitement.

DR. SPITZKA remarked that the rosy appearance of the patient did not exclude the presence of tubercular meningitis. He had not been able to elicit any history of malarial poisoning.

PATHOLOGICAL ANATOMY OF TETANUS.

DR. R. W. AMIDON read a paper upon the above subject, in which he gave an account of the microscopic changes which had occurred in the spinal cord of a man who had died of tetanus following compound fracture of the radius. The pia-mater was thickened, and contained a great number of very large cells—some fusiform, some multipolar, and some contained large nuclei. There were in the cord dark granular spindle-shaped cells, which were unaffected by carmine. There were hyperamia and thrombosis. There were cavities of various sizes in the nerve matter. The central canal was stuffed with epithelium. The changes were from simple vascular engorgement to disintegration, and affected the roots of the spinal accessory, trigeminus, facialis, hypoglossal, and glossopharyngeal.

DR. SPITZKA discussed the paper, and remarked that he believed the lesions described were secondary and not essential.

DR. AMIDON remarked that the significance of the lesions did not consist in the changes that had taken place so much as in the fact that they were confined to one locality.

MYSOPHOBIA.

DR. W. A. HAMMOND read a paper upon the above subject, in which he described a form of mental derangement that consisted in a *fear of defilement or contamination*. Ten cases had fallen under his observation, but not fully recognizing the exact nature of the earlier ones, he based his paper upon the complete clinical histories of the last three. In the first case described there was an overpowering desire to wash the hands, and in that occupation the patient spent a large share of her time. The fear of becoming contaminated gave her the most intense mental anxiety, suffering and distress; and although she was able to recognize the absurdity in her case, yet during her waking hours she was haunted and followed by what was to her a most terribly distressing fear.

In the second case the fear of pollution was more extended and serious, and the patient washed her hands as many as two hundred times a day.

The third case was equally well defined, but not so severe. When the patient visited the doctor's office she could not be induced to touch the door-knob when she was ready to leave the consultation-room, because of the tormenting and distressing fear of becoming contaminated, which held her in its complete possession. The treatment which he had exhibited had been to keep the bowels quite soluble by means of pills composed of podophyllin, aloes, and ox-gall; to administer bromide of potassium, sodium, or calcium, and in combination with opium if there was a tendency to melancholia; and to use tonics—such as cod-liver oil, strychnia, iron, and quinine.

DR. E. C. SEGUIN referred to a case in which the patient suffered through fear of croton bugs. The fear followed her, and she saw the bugs when it was well established that there were none present. She was cured by moral treatment and by tonics.

DR. SPITZKA spoke of phobia as a symptom which complicated different conditions, and

DR. KIERNAN mentioned cases of chronic mania in which he had seen similar symptoms.

DR. HAMMOND remarked that the cases which he had reported, and to which he referred, were not cases of insanity, for they had neither hallucinations nor delusions.

The Society then went into Executive Session.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Thursday Evening, April 3, 1879.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

AFTER the reading and adoption of the minutes of the preceding meeting, Dr. E. H. Janes, of the Committee on Admissions, reported favorably on the names of the following gentlemen, who were afterward duly elected Fellows of the Academy: Charles Miller, George T. Harrison, Samuel Sexton, David Webster, Frederick A. Castle, Henry F. Garrigues, of Brooklyn, Alexander J. C. Skene, of Brooklyn, George B. Hiccock, Thomas Kellogg, John T. Darby, and E. G. Janeway.

In the absence of the Librarian, Dr. Laurence Johnson, the Secretary, Dr. Hanks, announced for him that since his last report the Academy had received, as donations, 34 bound volumes, 38 pamphlets, 2 framed portraits, and a number of medical journals. Among the donors were mentioned the names of Drs. J. G. Adams, Albert H. Buck, Edward

H. Peaslee, Austin Flint, Sr., S. S. Purple, Fordyce Barker, and H. B. Sands.

The Corresponding Secretary, Dr. Adams, after making a brief report, announced the death of one of the Honorary Fellows of the Academy, Dr. George B. Wood, of Philadelphia, and read a sketch of his life and services, in the course of which he alluded to his long and distinguished career as a physician, and as Professor of the Philadelphia College of Pharmacy and the Medical Department of the University of Pennsylvania, his voluminous writings, both medical and historical, and their high reputation, and his generous endowment of five chairs in what is known as the "Auxiliary Faculty of Medicine," in his *Alma Mater*. It was stated that the great work on materia medica and therapeutics, entitled "The United States Dispensatory," and originally published in 1832, in which he was associated with Dr. Bache (but the greater part of which was written by himself), passed through fourteen large editions, and reached a sale of no less than 130,000 volumes; while his work on the Practice of Medicine, in 2 volumes octavo, published in 1856, passed through six editions. In 1871 he was elected an Honorary Fellow of the New York Academy of Medicine. He was, said Dr. Adams, emphatically a leader among medical men, and few have ever filled so large a sphere of usefulness or attained so high a position in the profession.

After a report from the Section of Obstetrics, Dr. Salvatore Caro, chairman, the Secretary read the details of a plan proposed by a special committee of the council, and recommended by the council in general, for the compounding of annual dues. It provided that any Fellow of the Academy in regular standing, who had attained the age of 30 years, might compound for all future annual dues by the payment of \$150; one who had attained the age of 35 years, by the payment of \$145; one who had attained the age of 40 years, by the payment of \$135; one who had attained the age of 45 years, by the payment of \$125; one who had attained the age of 50 years, by the payment of \$115; one who had attained the age of 55 years, by the payment of \$105; one who had attained the age of 60 years, by the payment of \$95; one who had attained the age of 65 years, by the payment of \$80; and one who had attained the age of 70 years, by the payment of \$55. Under the rules, the matter was laid on the table for one month.

The paper of the evening was then read by Dr. James R. Leaming, on

A NEW CLASSIFICATION OF PULMONARY PHTHISIS, WITH PRACTICAL CONSIDERATIONS.

The tendency of the present time, he said, was to rearrange, classify, and describe, with more detail, the various affections met with in the practice of medicine. As an instance of the advantage of this he cited the case of the so-called typhoid diseases, such as typhoid, typhus, and typho-malarial fevers, which were formerly considered but a single affection (this even being a decided advance over the extreme confusion that had previously prevailed) and were afterwards described, by Murchison and others, each as a distinct disorder, differing from the others of the group in its etiology, lesions, clinical history, and duration. That which had been so successfully accomplished in this class of affections remained to be done for the various forms of disease now known under the general name of pulmonary phthisis. He then quoted Sydenham's graphic delineation of the clinical characteristics of consumption, and remarked how little had been added to this description written two hun-

dred years ago! Laennec believed that, with scarcely an exception, all cases of phthisis were of a tuberculous character; while Broussais inclined to the idea of the ancients, that they were of an inflammatory nature. Laennec was deserving of all praise for his distinguished services, but, unfortunately, his well-earned fame had been instrumental in carrying some grave errors down to the present time. The more modern pathologists (particularly the Germans) had demonstrated that there were other forms of phthisis besides the purely tubercular, and their views had been adopted by many English and American authorities. Dr. Andrew Clark, in a lecture delivered at the Bellevue Hospital Medical College and reported in the *NEW YORK MEDICAL RECORD* of December 14th and 21st, 1878, divided pulmonary phthisis into three natural classes, and Dr. Leaming stated that he accepted his classification in part. The tuberculous and fibroid forms he regarded as not only distinct, but essentially opposite diseases, although they sometimes coexisted, and thus produced peculiar results. The classification which he had himself adopted, and which he now proposed to set forth, was founded both on clinical and *post-mortem* investigation. There were two principal forms of phthisis, he said, the tuberculous and the fibroid varieties. Under each class he enumerated two subdivisions, as follows:

I. TUBERCULAR PHTHISIS.

- (1.) *Uncomplicated tubercular lung.*
- (2.) *Tubercular lung with fibroid pleura.*

II. FIBROID PHTHISIS.

- (1.) *Fibroid lung and fibroid pleura.*
- (2.) *Fibroid lung and pleura, complicated with tubercle.*

UNCOMPLICATED TUBERCULAR LUNG

he believed to be a very rare condition. He had distinct recollections of but three cases of it, and no notes upon them. Louis had said that nothing was so frequent as adhesions of the lungs to the pleura, and out of one hundred and twelve cases, in only two were the lungs free from adhesions throughout their whole extent. In that form of phthisis the early history was very apt to be obscure, and the diagnosis difficult. Often the first sign only made its appearance after a cavity had been formed. It generally occurred in early adult life, and in those who had been living on poor food or surrounded by unwholesome sanitary conditions. In the early stage, when careful auscultation was made, a deficiency in the respiratory murmur, with slightly raised pitch, could be detected; but no râles. Neither was there any cough. When the tuberculous nodules softened, we had cough, expectoration, hectic, and all the well-known rational signs of phthisis. Then it was that fatal hemorrhage might occur from erosion of arteries.

When a cavity had been formed, the physical signs denoting its presence were not so plain as in fibroid phthisis, because the healthy lung tissue by which it was ordinarily surrounded was not a good conductor of sound. Wasting of the body commenced with the formation of cavities; and the case might end in general tuberculosis.

As to the treatment, that was of the greatest service which acted in the way of prevention. Chloride of ammonium was both a preventive and a curative agent; and cod-liver oil, quinine, the various other tonics, and change of scene and air, might all prove useful. If the heart's action was feeble and irregular, digitalis should be given, and atropia should be used to control night-

sweats. In the way of local measures, strapping with adhesive strips were of service, and small blisters might assist nature by inducing adhesions. If forced expansion was made when there were newly formed cavities, there was great danger of pneumorrhagia. Fatal hemorrhage rarely occurred after a cavity was a week old.

TUBERCULAR LUNG WITH FIBROID PLEURA.

In the second subdivision of Dr. Leaming we had tubercular concretions following fibroid in the pleura. In that there was a greater liability to fatal hemorrhage than in the other. The arteries seemed to be more easily eroded, and when the hemorrhage (which was apt to occur early in the disease) came it was almost always a surprise to the physician, as well as to the patient and his friends. The first indication of danger was the filling up of the nose and mouth with frothy blood, and the patient was literally drowned before anything could be done to relieve him. Another accident which might occur (and which was also liable in the first variety) was the causation of hydro-pneumothorax by an opening being formed into the pleural cavity as the result of the softening of a tubercular concretion. That gave rise to a great amount of pain and dyspnoea; and death was pretty sure to occur after a longer or shorter period. Recovery was rare after this condition has occurred. The diagnosis was sufficiently easy, and the indications in the treatment were to secure perfect rest (which could best be accomplished by strapping the chest), relieve pain, and control inflammatory action.

FIBROID LUNG AND FIBROID PLEURA.

In the first subdivision of the second class we had fibroid lung with fibroid pleura. Here was something, said Dr. Leaming, quite opposite to the tubercular process. That was really a destruction of tissue, while that was merely a destruction of function. It differed from the tubercular variety of disease also in being much more amenable to treatment.

The writer was of the opinion that nine-tenths of all cases of phthisis commenced with interpleural plastic exudation. Hence, the early recognition and treatment of that condition were of vital importance, and he believed that the day was not far distant when (on account of the more general adoption of that view) the mortality from phthisis would be much less than now.

In that class the disease always originated in fibrination of the pleura. That was the local starting-point; but there was always a predisposing cause in some depression of the vital force which might be due to various circumstances. Thus, any individual who had long been attendant upon the sick, the student unsuccessful in passing his examinations, the man of business perplexed with unusual care, the disappointed lover, the defeated soldier, were all peculiarly liable to be attacked with fibroid phthisis. In like manner, syphilis, masturbation, the sequelae of the various exanthemata, and similar depressing influences were prolific in its causation. The interpleural exudation, said Dr. Leaming, was a makeshift of nature, and it was often immediately re-absorbed. If it was not re-absorbed, however, it underwent organization and increased in extent; the result being that the pleura was pressed firmly down upon the air-sacs beneath.

The writer then went on to describe at some length the peculiar anatomical characters of the nutrient arteries of the lung, which, he believed, played a very important part in the history of fibroid phthisis, and

also satisfactorily explained some phenomena which would otherwise remain complete mysteries.

As fibrination went on, he continued, the patient gradually yielded before it. The outward form of the chest became more or less contracted and altered in shape, and the sufferer was obliged to stoop forward to prevent the racking cough that was so troublesome. Like some strong anaconda, the fibroid process was winding its ever-tightening coils about him.

Thus far the trouble had been confined entirely to the pleura; but in the second stage of the disease the fibrous bands extended down through the lungs themselves, and also involved the heart. Often a loud systolic murmur was thus occasioned.

The early physical signs were the same in each variety. Their distinguishing characteristic was soft tearing râles, which it required a somewhat practised ear to separate from the ordinary respiratory murmur beneath. When such signs could be made out, however, two facts were certain, viz., that there was plastic exudation in the pleura, and that the lungs were free. At the later stage of the process the râles were dry and crackling, and there was no trouble about making them out.

The treatment was simple and easy enough at the beginning of the trouble; but the longer the process went on the more difficult it became. Even if the exudation had existed for several weeks, however, the disease might be cured. Perhaps the most useful of all remedies here was the chloride of ammonium, which should be given in doses of from six to ten grains every waking hour. In addition, the patient should be surrounded by the best hygienic conditions, walk out in the country as much as possible, take deep and long inspirations to expand the chest, and live to a great extent on a milk diet. If these measures were unsuccessful, the bichloride of mercury in small doses should be tried, and Dr. Leaming believed that it acted as a tonic, as well as an alterant and solvent of adhesions. Some cases would not yield even to that, and then he advised the administration of mercurials to the point of salivation; which he thought had saved the life of the patient in a number of instances in his hands. In addition, small blisters would usually be of service; and, above all, chest-expansion should never be neglected. One of the best means of securing that, he believed, was to ride a fast-walking horse. Care must be observed, however, not to do violence to the adhesions that had formed by taking too active exercise. When from that cause, or as the result of any accident, pulmonary apoplexy ensued, complete rest should be enjoined, and the chest strapped with adhesive plaster. The advantages of climate and change of scene were also dwelt upon.

FIBROID LUNG AND PLEURA, COMPLICATED WITH TUBERCLE.

In the second subdivision of the second class were found the greater proportion of all patients suffering from phthisis. That form he believed to be also essentially fibroid; the tubercular element being a secondary phenomenon.

Niemeyer, said Dr. Leaming, made the statement that the greatest danger to be apprehended in catarrhal pneumonia was that it might become tubercular. We would say rather that that was the greatest danger to be apprehended in fibroid phthisis. As the result of that condition, the well-known symptoms of phthisis were noted—such as cough, chills, fever, night-sweats, wasting, etc.—and at length the characteristic expectoration announced the formation of a cavity. The physical signs were always very distinct here, on account of

the fibroid tissue in the lung and the hardened condition of the pleura. When the cavity had been formed, perhaps the patient might begin to sleep well, have an increased appetite, and feel better in every way; but there was seldom complete relief, and even if there was it was usually of short duration, for there were apt to be other tuberculous concretions undergoing softening at the same time.

Cavities in the lung, however, were not always of tubercular origin, as they might be due to fibroid disease, gangrene, etc., and might also be of traumatic origin. But to whatever causes it might be due the formation of a cavity in a fibroid lung was always of grave import, because it was so liable to become tubercular.

The treatment of that variety must consist in a judicious combination of that previously given for the fibroid and tubercular forms of phthisis. When the tubercular element had not already supervened, one supreme effort must be to prevent that complication. If, however, there were tubercular concretions, we must direct our attention towards preventing the extension of either form of disease. To that end the application of small blisters, and the confining of the patient to an exclusively milk diet for a time, were frequently of great service. Whenever fibroid phthisis was present we must endeavor to invigorate the vital powers, and Dr. Leaming, as before mentioned, fully believed in the tonic effect of mercury, as well as in its usefulness in carrying off effete products from the system. Of course caution must be observed in its use, but we need not deprive ourselves of its invaluable aid on that account. What would be thought, said he, of a surgeon who was afraid of a sharp knife?

The President, in announcing that the paper was now before the Academy, remarked that it showed great evidence of profound study and thought, as well as careful clinical observation, and that he hoped that the novel pathological and therapeutical views which it contained would elicit a full discussion on the part of the Fellows present. He would call first, therefore, on Prof. Flint.

DR. FLINT said that before coming to the meeting he was not aware what line of remark the paper would take. As the Chair had stated, the classification was a novel one, and he thought that a certain amount of study upon it would be necessary before one could intelligently adopt it. At present he was not prepared either to take issue with the writer or to accept his opinions. He recognized in Dr. Leaming a very zealous worker; but there was one pathological condition underlying his views, which, he must say, he believed to be erroneous, and that was the relations of pleurisy to phthisis. It had always seemed to him that the pleuritic disease met with in these cases was secondary to the pulmonary; while the writer regarded the pleuritic trouble as primary.

The classification of phthisis was a large subject, but he proposed to make but a very few remarks upon it on this occasion. Acute tuberculosis, he thought, must necessarily be considered as a distinct affection. So the purely fibroid variety of phthisis could be readily distinguished from other forms. Then there remained those cases of chronic lung-trouble, in which each of these elements seemed to enter to some extent; and it was difficult to know how to designate them.

The point at issue was, whether true miliary tubercles were present, and what was their relation to cases of chronic phthisis characterized by softening of the lung-tissue, the formation of cavities, etc. The views held as to this relation must, therefore, govern,

to a great extent, our adoption of any classification. At present he did not feel that he could conscientiously commit himself to any definite opinion in regard to the matter; and he was content to wait until further research should perhaps decide it. Such studies were to be based both on histological data and clinical data; but he believed the latter to be of really the most value.

Dr. Loomis thought that the paper deserved careful consideration, and that the views which it advanced should be discussed from different standpoints. Any satisfactory classification, he believed, should be based on three things: *first*, etiology; *second*, morbid anatomy; and *third*, clinical history; and it seemed to him very difficult to make such a classification in which these various points would not clash. The reason was, that the opinions of the scientific world as to some of the most prominent and constant histological changes observed in phthisis were not yet settled. If he understood Dr. Leaming properly, he took issue with the ordinary view that phthisis originated in the lung-tissue, and held that the primary changes in the disease occurred in the pleura instead. He did not understand, however, exactly what the writer meant by the term "fibrination," or the expression "plastic exudation undergoing organization." If we were satisfied in regard to any pathological facts, it was that all plastic material underwent absorption, and that the later changes observed, such as adhesions, fibrous bands, etc., were the result of a hyperplasia, or increase in connective tissue in the pleura, the pericardium or the peritoneum. At length, contractions took place in this tissue, and thus, when occurring in the pleura, they interfered more or less with the circulation and nutrition of the surface of the lung beneath. If Dr. Leaming were correct in his opinion, very great pathological changes must necessarily take place in the pleura before they were discoverable; for in a large proportion of cases important changes could be detected in the lung long before there was any evidence whatever of trouble in the pleura. It was a difficult question to decide where the primary trouble originated, because the *post-mortem* examinations necessary to settle it must be made at a very early stage of the disease. Where autopsies were made in the advanced stages it was rather an assumption to say where the difficulty commenced. Auscultatory evidence, he thought, would not answer, because good diagnosticians differed utterly as to the significance of various signs met with in the chest. Personally he believed in three forms of phthisis, as described by Dr. Andrew Clark in his lecture; although this classification had been known to New York long before the visit of that distinguished physician. He could satisfy himself better with that division than any other; but he certainly was not bigoted in his views, and was still open to conviction.

Dr. E. DARWIN HUDSON, JR., believed that pleurisy was one, at least, of the causes of phthisis. Every student, he said, must notice the occurrence of pleuritic adhesions, not merely in connection with the later, but also the early stages of phthisis. We were taught that in inflammation of the pleura the serous membrane became denuded of its epithelium, and then assumed a villous condition, when adhesions were apt to be formed. He believed that if adhesions were present to such an extent as to cause more or less contraction of the chest there would be definite and significant physical signs present, as had long since been recognized by Dr. Leaming. The latter was of the opinion that in a large majority of

cases of phthisis interpleural plastic exudation was the commencement of the trouble, and that when that was present it could always be detected by a soft subcrepitant r le heard directly under the ear, and comparable to the sound produced by the tearing of wet cloth. He had also the authority of Rindfleisch for saying that no case of pleurisy ever occurred without a certain number of the air-sacs of the lung beneath becoming consolidated.

Dr. E. G. JANEWAY was the last speaker. He remarked that the question as to how far pleurisy could originate tuberculosis must be looked at in two ways. He had sometimes seen cases in which acute disseminated tubercle undoubtedly resulted from pleurisy, by septic infection: a process which it was difficult to explain. He could recall two instances in which, when there was no trouble whatever in the lung, there had been a sudden eruption of tubercle throughout the body; but at the same time he did not believe that phthisis ordinarily was to be ascribed to pleurisy. On the contrary, he considered that autopsies every day showed that when trouble both in the lung and pleura were found, that in the lung was undoubtedly the older of the two. That was evident, he contended, in those portions where the process was most recent. To his mind, therefore, it seemed plain that we could not, in the majority of instances at all events, attribute the phthisis to interpleural exudation.

As to pure fibroid of the lung, he was of the opinion that it was very rarely met with. If by the term fibroid, however, was meant a thickening of connective tissue associated with the presence of lymphoid cells, that was a much more common condition. Pathologists were by no means agreed as to what tubercle really was, and hence a great confusion of terms had arisen; but there now seemed to be a gravitation of current opinion towards the view that tubercle was of more frequent occurrence than was for a time supposed. In the last edition of Niemeyer's work a considerable modification of the views expressed by that writer was noticeable, and Rindfleisch had gone further back towards the old ideas than any other authority. There was a growing appreciation at the present time of the necessity for the consideration of constitutional tendencies; and it seemed demonstrable that there was ordinarily more of tubercle in phthisical lungs than Virchow formerly taught. Even Virchow, he imagined, was returning, to some extent, to the adoption of views that had once been discarded.

Correspondence.

PROFESSIONAL ADVERTISING IN THE DAILY PRESS.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—Your correspondent, "Sic Nos," etc., has done the profession a service in calling attention to an abuse that appears to be rapidly extending. Hardly a week passes but one of the metropolitan journals contains a flattering notice of some favored member of the profession, and one journal in particular appears to have taken special pains to keep before the public the name of a prominent specialist in connection with certain "Talks to Young Men," etc. Just before reading the letter of "Sic Nos" in to-day's issue of the RECORD, I found in the *New York Times*

a notice, nearly a column in length, of a new medical journal, "Edited by Dr. E. C. Seguin." The notice commences: "This is a new medical journal, and having a man so distinguished as Dr. Seguin for an editor," etc. Farther on we read: "This brings us to the editorial department of the journal, in which we find, first, some valuable matter by the editor on diseases pertaining to the nervous system, for whose treatment he is particularly celebrated," etc. (italics our own). Now, sir, where is this thing to stop, and where is the line to be drawn? Have we still a committee of ethics, or did it go out of existence with the subsidence of the mineral-water excitement that called it into being? If that committee is dead, we think that an end can be put to this sort of thing if you will give the different gentlemen concerned a little additional gratuitous advertising by transferring to your columns the public press notices as they from time to time appear, and we trust that those who have the real welfare of the profession at heart will take the trouble to send you such clippings as fall under their eye.

NONNE?

MEDICAL REPORTS IN NEWSPAPERS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—The exceedingly incorrect report of my clinic which appeared in *The World* of April 18th, seemed to me to carry sufficient evidence on its face that I had nothing whatever to do with its production. But it seems I was mistaken, and that there are some over-sensitive, virtuous souls in a "state of mind" over this so-called breach of the code of ethics. Hence I desire to state most emphatically that I am utterly opposed to the publication of lectures and operations in the secular journals, as being calculated to lower the dignity of the profession, to bring it into disrepute, and to place the individual so advertised in the ranks of designing quacks.

The "crowd of spectators" present was simply a large assemblage of medical students from the city colleges, together with the nurses belonging to the Charity Hospital training-school. I invited no one who was not a practitioner of medicine to witness the operation. I had no idea that a word I said would ever appear in a public journal. I did not know that a reporter was in the building, or that any one was taking notes. No friend of mine had anything whatever to do with it. In short, I am not responsible for the report, directly or indirectly, in any shape or form.

Yours respectfully,

JOSEPH W. HOWE, M.D.

38 W. 24th STREET.

HOMŒOPATHIC CONFECTIONERY.—In some parts of Germany physicians are not permitted to dispense medicines, when there is an apothecary in the place to do it for them. We learn from the *Allg. Hom. Zeit.* that three homœopathic physicians were practising in Regensburg, when an apothecary of the same belief came among them and notified them to send their prescriptions to him. Two of them refused, and were brought before the court and fined about five dollars. The case was carried to a higher court, and the medicines (pellets) sent to the University of Erlangen for chemical analysis. The chemists of the university failed to find anything in them of a medicinal or poisonous nature, and so reported; whereupon the judge reversed the decision of the lower court, and declared that there was no law that prevented physicians from distributing sugar-plums (*Zuckerwaaren*) as freely as they chose.

New Instruments.

ON THE TREATMENT OF URETHRAL STRICTURE, WITH DESCRIPTION OF A NEW DILATOR.

BY GEO. M. SCHWEIG, M.D.,

NEW YORK.

THE literature on the subject of treatment of stricture of the urethra is so copious, the supporters of the various "radical cure" methods are apparently so sincere in their convictions and convincing in their arguments, that it is saddening to realize that they cannot all be right, and that the statistics of those who are wrong, though comprising innumerable cases, must of necessity be unreliable and deceptive. Until, therefore, discussion on the subject shall have finally ceased, and the matter settled beyond dispute, it behooves the practitioner to select the method that after a careful study of the subject may to him individually appear the most rational. Acting on this principle, I have always held that dilatation carried to a sufficient extent, is not only the safest method of treating the great bulk of cases of organic stricture, but the one which is at the same time the most likely to secure radical and permanent results. It were needless here to enter into an analysis of the reasons that led to my conclusions on the subject. I will only state, as a matter of justice, that the writings of Dr. Dittel, of Vienna, have been chiefly instrumental in originally shaping my views.

In endeavoring to put into practice the theories I adopted, I very soon realized the want of a perfect dilator for the urethra, and this want furnished a ready apology for the urethrotomist, in the impossibility to do full justice to dilatation. Far from discouraging me, the difficulties I encountered rather stimulated me to endeavor to surmount them. Whether I have succeeded must be for others to judge.

In devising an instrument that should meet fully the requirements of the surgeon, my ideal was: "(1) efficiency, combined with (2) perfect safety." Under the first head I claim for my dilator that it has the widest scope as such, being suitable alike for slow and gradual as well as rapid dilatation or over-distention (divulsion). Under the second, that its employment as a dilator is followed by no more reaction than that of an ordinary sound. This will become self-evident from the description to follow, which will also make apparent the absence of characteristics that rendered the employment of other dilators either dangerous or inefficient, or both. I am indebted to Messrs. Geo. Tiemann & Co. for their kind and ready aid through a long course of wearisome experimenting to the final completion of the instrument.

The accompanying woodcut shows in Fig. 1 the dilator closed; in Fig. 2 the dilator open. A (Fig. 1) shows the shaft of the instrument. As this is not intended to enter the bladder, it has not the curve of the ordinary sound. To facilitate introduction, however, its (conical) point has a modification of Mercier's curve. The length of the entire shaft is about twenty centimetres, but can be made any desired length. It is graduated in half inches, the measurement beginning at the centre of the dilating wedge (b). It is hollow, and contains the rod and levers that force out the dilating wedge.

This last (b) is three and a half to four centimetres

in length, and of a width equal to the diameter of the shaft, thus offering a *broad* dilating surface. It is enclosed on all sides except the one facing the interior of the shaft, or, in other words, on every side that protrudes into the urethra when the instrument is being used. It thus presents a smooth, solid, continuous surface to the urethra when protruded, leaving nowhere a crevice or opening for the engagement of any mucous membrane. When the instrument is closed, the wedge does not project, but is level with the shaft. It is forced out by two levers attached to a rod, which runs the length of the shaft, and is in turn attached to the screw-wheel (*d*), by means of which the instrument is worked. I had two levers made, one at each end of the wedge, rather than only one, thus insuring steadiness and parallelism to the wedge. At *e* there is an index (French scale) that shows the degree of dilatation at every stage of the operation; *cc* are ring handles to steady the instrument and keep it in place.

The instrument can be made of any required calibre. It must be remembered, however, that the degree of dilatation attainable is in direct ratio to the size of the shaft; for it will readily be understood that the hollow shaft can contain no wedge larger than its own cavity without destroying continuity of outline.

Rationale of Treatment.—I presume no one will dispute that in the meatus we have the main ob-

stacle to successful (curative) dilatation by means of sounds. There are comparatively few strictures that will not admit of palliative dilatation, *i. e.*, dilatation carried up to the full extent of what the meatus will admit. When this point is reached, however, we find ourselves compelled either to cut the meatus—that is to say, to produce an abnormal condition, or else to substitute for the sounds some other mode of treatment. It is here that we have to choose between the dilator and the urethrotome, and I believe that, with an in every respect satisfactory dilator at his command, no surgeon who has familiarized himself with the subject on an anatomical as well as clinical basis, will hesitate in his choice. If I have succeeded, as I believe I have, in producing such an instrument, then there will—with the exception of special cases, such as bands, valvular strictures, etc.—be in the future no necessity or justification for internal urethrotomy, with its attendant dangers and doubtful results.

With my instrument the treatment of stricture can go on uninterruptedly. When the largest size sound has been reached that will enter the meatus with ease, I simply substitute a dilator one or a few sizes smaller. In this way not only is the difficulty of the meatus obviated, but the treatment becomes at once superior to that by large sounds, as these, before entering the stricture, push this before them, while the dilator, being a few sizes smaller, enters the stricture readily, and, when engaged, dilates at right angles.

The instrument dilates to about two-fifths of the number represented by the shaft over and above this. Thus I have a number 25 that dilates to 33, a 30 that dilates to 43, a 28 that dilates to 40, etc., etc.

The *modus operandi* is sufficiently simple. The exact location of the stricture having been determined,

ably to the broad surface of the dilating wedge. Before withdrawing the instrument, the screw must, of course, be turned all the way back to allow the wedge to sink back within the shaft.

The instrument is so constructed that, after use, the wedge can be removed entirely, and both it and the shaft thoroughly cleaned.

I have no desire to draw comparisons between this and other instruments designed for the same purpose. I will therefore conclude with a brief summary of its chief characteristics, which are:

1. Simplicity of construction and mechanism.
2. The screw and lever plan, insuring irresistible strength and uniformity of pressure.
3. Dilatation parallel and at right angles.
4. A broad dilating surface.
5. Ease of introduction and extraction.
6. Facility of cleaning.
7. Reliability as to dilating at the proper place.
8. Restricting dilatation to the strictured portion and its immediate neighborhood.

9. POSITIVE AND ABSOLUTE IMMUNITY OF THE MUCOUS MEMBRANE.

435 LEXINGTON AVENUE.

ACUPUNCTURE.—This mode of counter-irritation, which has rather fallen into disuse, is being recommended to the profession again. In rheumatic and neuralgic pains it is often extremely efficient.

LONDON PATHOLOGICAL SOCIETY.—Drs. Charcot, Chauveau, Robin, Chonheim, Thiersch, Pirogoff, Schwann, Rindfleisch, and Gross were elected honorary members of the London Pathological Society, November 19th.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from April 20 to April 26, 1879.

STERNBERG, G. M., Major and Surgeon. Relieved from duty in Dept. of the Columbia, and to report in person to the Surgeon General for temporary duty. S. O. 95, A. G. O., April 19, 1879.

The following medical officers will represent the Medical Department of the Army at the annual meeting of the American Medical Association at Atlanta, Ga., on May 6th next: Surgeons J. J. WOODWARD, J. S. BILLINGS, WM. H. FORWOOD, and Asst. Surgeon R. M. O'REILLY. S. O. 97, A. G. O., April 23, 1879.

THE AMERICAN ASSOCIATION FOR THE CURE OF INEDRIATES will hold its tenth annual meeting in the parlors of the Young Men's Christian Association, Twenty-third Street, New York City, May 13th and 14th. A very important meeting is expected.—T. D. CROTHERS, Sec.

SIXTH DECENNIAL PHARMACOPŒIA CONVENTION.—To the several Incorporated State Medical Societies, the Incorporated Medical Colleges, the Incorporated Colleges of Physicians and Surgeons, and the Incorporated Colleges of Pharmacy throughout the United States: By virtue of authority devolved upon me, as the last surviving officer of the Pharmacopœia Convention of 1870, I hereby call a general convention to meet in Washington, D. C., on the first Wednesday in May, 1880, for the purpose of revising the Pharmacopœia of the United States. For the information and guidance of all parties interested I refer them to the rules adopted by the Convention of 1870, to be found on page 11 of the Pharmacopœia of the United States, and request their compliance with the spirit and intention of the said rules.—JAMES E. MORGAN, M.D., No. 905 E Street Northwest, Washington, D. C.

THE U. S. STEAMER "PLYMOUTH" AND YELLOW FEVER.—The Surgeon-General of the U. S. Navy has furnished the following facts in regard to the recent outbreak of yellow fever on the U. S. steamer "Plymouth": on November 7th last, four cases of yellow fever occurred on board the vessel while lying in the harbor of Santa Cruz; these were removed to hospital on shore, and the ship sailed for Norfolk. Three mild cases occurred during the voyage, and the "Plymouth" was ordered to Portsmouth, N. H., thence to Boston. At the latter port everything was removed

from the ship, and all parts of the interior freely exposed to a temperature which frequently fell below zero, the exposure continuing for more than a month. During this time the water in the tanks, bilges, and in vessels placed in the store-rooms, was frozen. One hundred pounds of sulphur was burned below decks, this fumigation continuing for two days, and the berth-decks, holds, and store-rooms were thoroughly whitewashed. On March 15th the ship sailed from Boston southward; on the 19th, during a severe gale, the hatches had to be battened down, and the berth-deck became very close and damp. On the 23d two men showed decided symptoms of yellow fever, and on the recommendation of the surgeon the vessel was headed northward. The sick men were isolated, and measures adopted for improving the hygienic condition of the vessel and crew. The surgeon reported that he believed the infection to be confined to the hull of the ship, especially to the unsound wood about the berth-deck, all the cases but one having occurred within a limited area; and that while the "Plymouth" is in good sanitary condition for service in temperate climates, should she be sent to a tropical station probably no precautionary measures whatever would avail to prevent an outbreak of yellow fever.

J. B. HAMILTON,
Surgeon-General U. S. Marine
Hospital Service.

A SINGULAR RENAL CALCULUS.—Dr. A. E. Lowenthal sends us an account of a very rare form of renal calculus found, accidentally, while dissecting. The calculus filled the whole pelvis of the right kidney and was accurately moulded to the infundibula and calices. It was composed of phosphates covered with a thin layer of uric acid. The kidney itself was two-thirds the normal size and the seat of a chronic diffuse nephritis. The left kidney was enormously hypertrophied and perfectly healthy. The patient died of a pleuro-pneumonia. The history of the symptoms caused by the calculus could not be obtained.

FUNIS PRÆVIA AND THE GENU-PECTORAL POSITION.—Very strong testimony to the value of this position is given by W. J. Burge, of Pawtucket, R. I., who sends the following case: He was called to attend a patient in her third labor, and found the os dilating and the head resting on the anterior brim of the pelvis. Through the membranes the cord could be felt pulsating. The membranes were after a time ruptured when great prolapse of the cord took place. The head remained on the brim of the pelvis, and the labor pains were ineffectual. The patient was placed in the knee-chest position, the hand passed into the vagina, and the cord pushed back into the uterus. The pains immediately drove it out, however, and the first attempt was unsuccessful. After waiting a while a second effort was made, the cord was pushed back with one hand and pressure made over the pubes with the other. This time a strong contraction immediately ensued, the head engaged in the strait, the cord remaining up, and in half an hour the child was born alive. Dr. Burge asserts that he cannot be too grateful for Thomas's position; it has served him admirably in three cases.

A PERFUMED SOLUTION OF IODOFORM.—Shake tincture of iodine with a fragment of fused potassa till the color be removed. Cover the odor of the iodoform thus produced by the addition of eau de cologne. Dip lint in this solution, allow it to dry, and one will have an agreeable and excellent application for indolent ulcers, fissure ani, burns, etc.

Original Lectures.

THE PERSONAL IDENTITY OF THE LIVING AND OF THE DEAD.

TWO LECTURES DELIVERED BEFORE THE CLASS IN THE AUXILIARY DEPARTMENT OF MEDICINE.

By JOHN J. REESE, M.D.,

PROFESSOR OF MEDICAL JURISPRUDENCE AND TOXICOLOGY IN THE UNIVERSITY OF PENNSYLVANIA.

(Reported for THE MEDICAL RECORD.)

LECTURE I.

THE PERSONAL IDENTITY OF THE LIVING AS ESTABLISHED: 1. BY DIRECT EVIDENCE; 2. BY PECULIARITIES IN APPEARANCE; 3. BY MEANS OF THE VOICE; 4. BY THE PRESENCE OF PECULIAR MARKS; 5. BY INFERENCE. —THE IDENTIFICATION OF THE DEAD: 1. WHEN THE INDIVIDUAL HAS DIED RECENTLY; 2. WHEN THE SOFT PARTS HAVE ALL DECAYED. —THE AID AFFORDED BY CHEMISTRY AND THE MICROSCOPE, ETC.

Among the various subjects claiming the attention of the medical jurist, that of *personal identity* is by no means the least important. Cases are constantly occurring in the courts of law in which this question of identification comes up as a most important factor in the evidence. For example, it becomes necessary for a person who has been assaulted or robbed, to be able to identify the assailant or robber, when on trial; a witness is strictly examined as to the identity of a person or persons with whom he is acquainted; an alleged child or heir of an estate is compelled to establish his personal identity before the courts before his claim can be sustained, etc. And then, in relation to persons *found dead*—whether in cases of recent death, when the body has undergone but little change, or years after the decease, when nothing remains of the body but the bare skeleton from whence to glean the important information—the question of personal identity acquires the most intense interest, more especially in a trial for murder, where it becomes essential to establish the identity of the alleged victim as the *corpus delicti*.

It is true that the aid of the physician is not so frequently invoked for proving the identity of the living, since this can generally be equally well established by other persons, as friends and neighbors, as by a medical man. Still, there may be occasions of unusual complexity in which a professional opinion may become requisite, as, for example, to verify certain deformities, fractures, scars, and other marks about the person, when there are the evidences on which the identification may be dependent.

I shall consider this subject under the two divisions of: 1. *the identity of the living*; and 2. *the identity of the dead*.

THE IDENTITY OF THE LIVING, AS ESTABLISHED:

1. *By Direct Evidence.*

This may usually be established, 1, by the *direct evidence* of witnesses who have known the person long enough to have had his appearance sufficiently impressed on their memory: such is the testimony of acquaintances, neighbors, friends, and relatives. Although among the myriads of the human family it is

very rare to find any two persons exactly alike in all points, yet remarkable instances have occurred where the personal resemblance has been so striking as to have baffled even the skill of the detective; and this resemblance has been made even still stronger by the existence of similar marks, cicatrices, or certain peculiarities of structure in both individuals. Some striking illustrations could be given of the extreme difficulty—amounting at times to an impossibility—of deciding the question, which also show how easily witnesses may be mistaken in their evidence on this subject. I shall only refer to two. In the year 1560 the celebrated case of *Martin Guerre and Arnaud du Tilh* was tried before the Parliament of Toulouse, France. Martin had been away from his home for eight years, when the person named du Tilh appeared, and represented himself as the long absent man. So great was the resemblance, that his statement was universally accepted by all of Guerre's family, including his wife, four sisters and two brothers-in-law, among whom he lived unsuspected for three years. About this time, however, something occurred to excite suspicions as to the true character of the supposed husband, when he was arrested and brought before the tribunal on a charge of fraud. Upon his examination he gave satisfactory answers to the most minute questions in relation to Guerre's former life. Some one hundred and fifty witnesses were examined during the investigation, of whom between thirty and forty testified, from a lifelong acquaintance, that the prisoner was Martin Guerre, while about the same number swore positively that he was Arnaud du Tilh, whom they well knew; and over sixty, who knew them both, declared that they were unable to say which the prisoner was. Finally, however, the real Martin Guerre appeared upon the scene, when immediately he was recognized; the four sisters who had previously testified that du Tilh was their real brother now admitted their error, and acknowledged the distinction. There being now no doubt of the guilt of the prisoner he was condemned, and afterward executed.*

The other instance is afforded in the recent famous Tichborne case, in which an individual named Orton, with various aliases, undertook to personate an English baronet and heir to a large entailed estate. So successful was his scheme that "he was sworn to be Sir Roger Tichborne by eighty-five witnesses, among whom were Sir Roger's mother, the family solicitor, one baronet, six magistrates, one general, three colonels, one major, two captains, thirty-two non-commissioned officers and privates in the army, four clergymen, seven tenants of the Tichborne estates, and seventeen servants of the family." The claimant also gave proof of "a fish-hook wound on the eye, of a mark of bleeding on the ankle, and of a peculiar scar on the head," all of which the genuine Sir Roger possessed. The case, however, broke down on cross-examination, many circumstances being proven against the claimant, which I have not now the time to enumerate. Suffice it to say that a verdict was taken against the claimant, and that an indictment was since found against him for perjury.

Now, as a fair inference from the above two remarkable cases, I think we may assume that appearances are *not* conclusive evidences of identity. In the language of a writer in the *London Spectator*, "a very large proportion of ordinary persons are very untrustworthy witnesses to identify, when dependent on appearance alone. They are, either from nature or habit, incapable of appreciating *form*, and form alone is the

*Wharton & Stille's Med. Jurisp., Vol. 11, p. 1092.

unerring proof of personal identity. The difficulties in the way of identification, more especially of the dead, are to them insuperable." This writer, moreover, suggests, as a reason for this difficulty in identification from mere appearance, what seems sufficiently plausible, "that something like color-blindness affects this matter of identification; that there is a large number of persons whose evidence upon any question of identity, though perfectly honest, is worthy of very little trust; that men, upon this, as upon most other matters, are guilty of an unconscious carelessness like that which makes testimony about figure statements so often valueless."

A remarkable instance of what has been named false evidence of *diversity*, as distinguished from that of identity (and honestly supported), is afforded in the case of Lord Aberdeen, the young English nobleman who was drowned in this country a few years ago. This young man, heir of one of the oldest British peerages, and of excellent personal character, was seized with a romantic passion for a sailor's life. He came over to New England, and, under an assumed name, threw himself among common seafaring men, acquired their language, and adopted their habits and pursuits, so that he passed among them as a companion of their own social order, with perhaps some advantage of former education. One day he was lost overboard in a storm, and was drowned. Soon afterward search was made for the missing nobleman by his friends and family in England, no expense or pains being spared to ascertain the particulars of his death, and especially to establish the *fact* of the death; but it was, I believe, found to be exceedingly difficult, if not impossible, to procure such evidence from his sailor companions (who regarded him merely as one of themselves), as would seem to identify him as the heir of an earldom. This case will serve to illustrate what is called by another "the vehement antagonisms of evidence in cases of disputed identity."

2. *By Peculiarities in Appearance.*

A second means of establishing the identity of the living, especially in a criminal, is by certain peculiarities in the appearance which are noticed at the time of the commission of the crime, and which are therefore apt to leave a strong impression on the senses, such as (*a*) *size*, when the individual is very tall or very short, very corpulent or very slim; (*b*) *dress*, where a portion (sometimes it may be a mere shred) of the prisoner's dress is discovered near the seat of the crime, which exactly corresponds with the rest of the garment found in his own house.

3. *By Means of the Voice.*

A third means is by the *voice*. Peculiarity of voice always makes a strong impression upon those who observe it, and constitutes a valuable aid in identification.

4. *By the Presence of Peculiar Marks.*

A fourth means is by the presence of certain peculiar marks, either natural or acquired, about the person, such as moles, scars, cicatrices, deformities, fractures, etc. Such marks are usually well known and remembered by the friends and neighbors of the individual, who can usually identify them. Some of these remain upon the body during life; others gradually decline and fade away. In relation to *tattoo-marks*, Prof. Casper's opinion is that some of them (the red ones) are gradually obliterated by time, whilst the black and purple ones are more permanent. A cicatrix is permanent during life if there has been

any original loss of substance. It may not always be distinguished from the surrounding skin until the part be smartly rubbed, when the white scar is immediately manifested on the red surrounding skin. You should be cautioned against too strong a reliance upon scars as a means of identity, since these may at times be discovered upon another precisely alike, both in form and situation. Under this head I would also mention the appearance of the *hands* as often indicating the nature and character of the occupation of the individual.

Photographs and other *portraits* of the suspected person are sometimes useful aids in the identification of the living as well as of the dead.

5. *By Inferential Evidence.*

Another valuable means of establishing identity is by *inferential evidence*; as when a person strongly resembling the accused was seen in the neighborhood of the alleged crime. Also by *footprints* which are shown to exactly correspond with the boots of the accused, and by impressions made on the ground by other parts of the body, as the knee, and which correspond with prisoner's dress. I may mention, finally, under this head, certain *suspicious circumstances* connected with a criminal which may go far in establishing his identity; such as some peculiarity in his conduct noticed about the time of the commission of the crime; evidence of his having used his *left* hand in an assault upon another or upon himself, if found to be left-handed; a connection between the prisoner and some article found near the scene of crime, as a weapon, or a bullet which exactly fits a mould in his possession, or the wadding of a gun shown to be composed of paper a portion of which is discovered still in his possession, etc.

THE IDENTIFICATION OF THE DEAD.

This may have reference (1) to the body recently dead; and (2) when the soft parts have disappeared by decomposition, and the skeleton only remains, or detached bones merely have been discovered.

1. *When the Individual has Died Recently.*

If the body is found unutilated, many of the same general methods for establishing its identity are available as have already been mentioned in the case of the living; such as the testimony of friends and acquaintances as to the personal appearance of the deceased; clothing; certain marks upon the person, as moles, navi, cicatrices, deformities, fractures, tattoo-marks, etc. Photographs and other portraits are also admissible, but are by no means reliable proofs.

If the body, after death, has been subjected to mutilation, and the severed portions removed to a distance from one another, and some of them even destroyed, as is sometimes done by a murderer, with a view to escape detection, the difficulty of identification is, of course, much increased; nevertheless, if the disconnected parts can be recovered, or even a portion of them, it will always be possible for a skilled anatomist so to readjust them as to build up the body again, as it were, by making the proper allowances for the deficient parts, and comparing these with other average specimens. Several striking examples of this are given in the books; I shall allude to only two. One of these is a well-known case which occurred in this country about thirty years ago—that of Dr. Parkman, who was murdered by Dr. Webster, of Boston, Mass. After the death of his victim, Dr. Webster attempted to destroy all evidences of the deed by cutting

up the body into fragments, some of which were burned in a grate, some immersed in chemicals, and others packed away in boxes in distant parts of the building. On the discovery of these remains, a week after the murder, the portions of the body were accurately examined; it was proved that they were human remains, of one and the same body, and of the male sex; and that they had not been dissected for anatomical purposes, but cut and hacked in different directions, for the object merely of mutilation. On restoring these parts *in situ*, and supplying the deficient portions, the proper measurements agreed closely with those of the missing Dr. Parkman. This circumstance, together with the discovery of certain marks of identity about the teeth and jaws (the head had been almost completely destroyed by fire), afforded sufficient evidence of the personal identity of the missing gentleman to enable the jury, on the trial of Dr. Webster, to find a verdict of guilty. The other instance is that recorded by Dr. Taylor, in his work on Medical Jurisprudence. A number of years ago a murder was committed on the river Thames, and a short time afterward a package containing mutilated human remains was found on one of the abutments of the Waterloo bridge. The murderer had, no doubt, intended to throw this bundle into the river, but it had been arrested in its descent. Dr. Taylor was asked to identify these mutilated remains; and when, after great difficulty, the parts were brought together, and found to fit, the body was identified as that of the murdered man—a Swedish sailor.

2. *When the Soft Parts are all Decayed.*

When the question of identity relates to the skeleton merely, or to portions thereof, the answers cannot always be so satisfactory; and the medical jurist has need of much caution and reserve before giving a positive opinion.

The very first thing for him to determine is whether the bones submitted to his inspection are human, or do they belong to some of the lower animals. Certainly, if the entire skeleton is discovered, there need be no doubt whatever on the subject; but if only a single bone or two be found, a mistake may easily be made, except by a practised anatomist. Indeed, some ludicrous blunders are recorded of persons of education mistaking the bones of the ox, horse, dog, pig, and goat for those of the human subject.

The Aid afforded us by Chemistry and Microscopy.

But you will no doubt ask, will not chemistry and microscopy assist us in such an instance? As regards the former science, I can at once and positively answer, no. The bone of man has precisely the same chemical elements as that of any other animal. The microscope does throw a little light upon the subject. The bone-cells, or corpuscles, are of different sizes in the various orders of animals. They are largest in the reptiles, and smallest in the birds. There is a striking analogy between the size of the bone corpuscles and that of the red blood-corpuscles among animals. The red blood-corpuscles of the reptiles are largest, and those of the birds smallest. The bone-cells of mammals occupy an intermediate position. The bone-cells of fishes are altogether different from those of all other animals. But, having had this much assistance, the microscope cannot distinguish the bone-cell of a man from that of any other mammal, for the bone-cells of the mouse, of the elephant, and of man are all alike; hence you see that the knowledge which the microscope gives us here is not of so much value after all.

Original Communications.

ON THE MECHANICAL TREATMENT OF CHRONIC INFLAMMATION OF THE HIP, KNEE-, AND ANKLE-JOINTS,

BY A SIMPLE AND EFFICIENT METHOD—THE PHYSIOLOGICAL METHOD—WITH CASES.

BY JOS. C. HUTCHISON, M.D.

(Read before the Kings County Medical Society, March 18, 1879.)

I DESIGN in this paper to describe a plan for the mechanical treatment of inflammation of the hip-, knee-, and ankle-joints by methods which seem to me to be more simple, effective, and agreeable to the patient than those hitherto employed.

It may be stated at the outset that morbid conditions of the joints are, as a rule, essentially chronic, and whether the disease originates in the synovial membrane, the cartilages, bones, or investing fibrous capsule, ultimately the morbid action involves all the tissues, so that, without the previous history as a guide, it is often impossible to determine in what tissue the inflammation began. It is to my mind merely a pathological refinement, in most cases, of joint disease, especially in childhood, to attempt to describe the symptoms indicating distinct pathological states of the individual structures composing a joint. The treatment would be essentially the same whether one or all of the articular structures are simultaneously involved.

The indications for the mechanical treatment of inflammation of the joints of the lower extremities are to secure *immobility, extension, the removal of the superincumbent weight of the body, and means of enabling the patient to take open-air exercise.* The accomplishment of these indications, and the use of judicious medication and proper hygienic influences, comprehend all the principles of treatment.

Immobility of an inflamed joint, absolute and complete, is a primary and essential condition of its local treatment. The more effectually this is secured, the more rapidly and perfectly the joint recovers its normal condition, and the less danger there is of its being permanently damaged. The greatest obstacle to recovery is friction of the inflamed surfaces. I do not mean a mere limitation of the movements of the joint—such “rest” as is obtained by placing the limb upon a soft bed or pillow—but the perfect fixation secured by a splint or other means, which admits of no motion whatever. I am aware that many excellent surgeons believe that the danger of irreparable structural change and ankylosis of the joint is very great from prolonged fixation. This I am sure is an error. There may be a temporary ankylosis, such as arises from a diminution of the elasticity of the articular cartilages, and an enfeebling of the ligaments and muscles from disuse; but such changes are, or need be, only temporary, for by careful and steadily increasing use, reparation takes place in all these structures, and after a time they show no defect. I have never seen true ankylosis when the joint has been immovably fixed until the inflammation has subsided, except in cases of extensive destruction of the joint structures, in which case a cure by ankylosis is the thing to be desired. Exceptional cases no doubt occur, but the ankylosis takes place more commonly when fixation is incomplete, and more or less motion and friction

are permitted before the inflammation has entirely subsided.

The object of extension is (1), to correct the malposition of the limb. An inflamed joint is never straight; it involuntarily becomes flexed, nor is it possible for the patient to prevent or change this position. The flexion takes place slowly, almost imperceptibly, but surely, even when the limb has been permitted to rest quietly in bed undisturbed either by the patient or nurse; the degree of flexion depends upon the intensity or the duration of the disease. Every joint, when it becomes inflamed, assumes a characteristic *position* which it is important to know, not merely as a diagnostic sign, but also as a point which may be made useful in treatment. When the *hip-joint* is inflamed, the thigh is flexed on the pelvis, and, as a rule, is slightly adducted. The *knee-joint*, when inflamed, is always flexed more or less. In the case of the *ankle-joint*, the foot is flexed upon the leg, the heel is raised by the gastrocnemii, and the toes pointed downward. The *improper position* which the joint assumes should be corrected as soon as possible, even when the inflammation is acute; this is important in order that the different structures of the joint may not be kept in a state of undue pressure, or of inordinate tension, either of which interferes with healthy nutrition, and so conflicts with the curative process. As the joint becomes straightened under the influence of extension, the patient experiences an almost immediate diminution of pain. (2.) By means of extension we also overcome the spasm and contraction of the muscles, which, by reflex contraction, jam together the inflamed articular surfaces, and is the chief cause of pain in joint inflammations; but I do not believe it possible, by any amount of extension that can be applied, to separate the inflamed and swollen interior surfaces of the joint so as to relieve them from pressure and the consequent pain. What we do accomplish by extension is the relief of spasm and muscular shortening; and to quiet the muscles is an imperative therapeutic axiom.

The necessity for securing the beneficial effects of out-door air by means of some portable apparatus which removes pressure from the inflamed joint is now so generally appreciated that we need not urge its importance.

The special methods of meeting the above indications will be described when we consider the treatment of the diseases of particular joints.

HIP-JOINT DISEASE.

The American Journal of the Medical Sciences for January, 1879, contains an article by the writer "On the Treatment of Morbus Coxarius by a New Method of Extension; the Physiological Method; with Cases," and I propose on this occasion to illustrate the method by exhibiting some patients who are now undergoing the treatment, and to show that the various kinds of portable apparatus now in use do not accomplish what is claimed for them. It is my purpose also to demonstrate that the "physiological method of extension" is quite as useful for the treatment of inflammation of the knee- and ankle-joints as it is for morbus coxarius.

For many years Harris, of Philadelphia, and others, treated morbus coxarius in bed by extension and fixation of the joint with the long splint formerly used for fracture of the thigh, with moderately satisfactory results; and in 1855, Dr. H. G. Davis, of New York, described a new portable apparatus designed to produce extension while allowing motion of the joint, and permitting the patient to enjoy the benefits of out-

door exercise, so important in the treatment of this disease. It was claimed also by Davis and his followers that confinement to bed with the long splint applied, fixing the joint, not only impaired the general health, but increased the risk of ankylosis, which would leave the patient in a worse condition than if left to the tender care of Nature herself.

This new method of treatment awakened the interest of surgeons generally, and very soon afterward Sayre improved or modified Davis's instrument, and, with the enthusiasm of an ardent nature, brought the new treatment prominently into notice, and by papers and lectures did more to secure its general adoption than the originator himself had done. The instruments of Taylor, Vedder, Washburn, and that devised by myself, are also modifications of Davis's, designed to accomplish the same indications, viz.: *mobility of the joint with extension*.

Barwell, Andrews, of Chicago, Bauer, now of St. Louis, and Thomas, of Liverpool, believe that the indications for the proper treatment of the disease are to secure *immobility of the joint with extension*, and they have respectively devised very ingenious instruments to accomplish this purpose; while Professor Hamilton's wire-gauze apparatus was designed merely to secure *immobility of the joint without extension*.

All these appliances are familiar to you, except that of Thomas, of Liverpool, which I will briefly describe. It consists of a flat piece of malleable iron, from three-quarters of an inch to an inch in width, by one quarter in thickness, which extends from the lower angle of the shoulder of the affected side in a perpendicular line downward to the calf of the leg. A strap of hoop-iron is riveted to the top of the upright, and nearly encircles the body a little below the axilla; another strap of iron, half the circumference of the thigh, is fastened to the upright just below the fold of the buttock; and a third, half the circumference of the calf, is riveted to the lower extremity of the upright. The instrument is carefully moulded to the inequalities of the body by means of wrenches, and is well padded and covered with leather. The apparatus having been applied, the patient is allowed to walk on crutches with a patten on the sound foot, so as to elevate the diseased limb two or three inches from the ground.

This apparatus will not permit the patient to sit down, and renders defecation very inconvenient.

We have therefore three classes of portable appliances in use for the treatment of morbus coxarius, all of which, with due respect to the ingenuity of their respective authors, I feel called upon to condemn: (1), because they do not achieve the objects for which they are designed; and (2), if they did, they are cumbersome and uncomfortable, and therefore should be abandoned, because the same indications can be accomplished by a method simpler and more comfortable to the patient.

The theory that motion and extension are obtained by the apparatus of Davis and his followers is a great deception. If you notice a patient wearing Taylor's or Sayre's long splint (modifications of Davis's), those most frequently used here, you will see that when he walks the whole pelvis swings, and there is no motion at the hip-joint.

This immobilization of the joint a kind Providence has secured, in spite of the efforts of the surgeon to prevent it. You will also observe that there is no extension made by the instrument, as the inventors claim, because the strap which is designed to produce extension, and passes from the ends of the adhesive plaster beneath the extension bar, is slackened

at every step. This I have noticed lately in a number of cases in one of the hospitals of the city of New York, where there is a large orthopædic ward under the care of an accomplished orthopædic surgeon, who uses Taylor's apparatus. The instrument merely transfers the weight of the body from the hip-joint to the perineal band, but the extension is made by the weight of the limb alone.

The apparatus of Andrews, Barwell, and Bauer are equally inefficient in securing the objects for which they were designed; viz., to render the joint immovable and to produce extension of the limb. Thomas's instrument, by its long leverage, extending from the angle of the scapula to the calf of the leg, has some control over the movements of the joint; but it is unnecessary for this purpose, and, as already indicated, is very inconvenient to the patient; while the wire-gauze apparatus of Prof. Hamilton can have but little influence in producing immobility, because it does not extend far enough above and below the joint.

Why is it, then, it may be asked, if the appliances referred to are insufficient to accomplish what is claimed for them and are deceptive, that so much improvement has been reported from them when compared with others not having their features? For my own part, I am in the habit of explaining these favorable results by the fact that the use of the instruments devised by American ingenuity has liberated patients from in-door constraint, and enabled them to live and move and exercise in the open air, instead of being treated in bed as was formerly done; and also from the fact that the principal indications, immobility and extension, are achieved in spite of the apparatus used.

We have already considered the indications for the treatment of hip-joint disease, and also for the treatment of inflammation of the knee- and ankle-joints. They are: (1), to secure immobility of the joint; (2), to make extension; (3), to take off the superincumbent weight of the body; (4), to provide means to enable the patient to take open-air exercise; and I desire to demonstrate that they can be accomplished with comfort to the patient and convenience to the surgeon by the simplest expedients.

The method of treating hip-joint disease which I commend to your attention, after having used it exclusively for the last two years, is illustrated on the little patient before you (Figs. 1 and 2). To the shoe of the sound limb a steel plate, corresponding to the sole of the shoe, is attached by upright rods two and a half or three inches in length, so as to raise the foot from the ground; it is the shoe ordinarily used for shortened leg. This elevated shoe and a pair of crutches constitute the apparatus. As the patient stands on his crutches the diseased limb is suspended. The shoe is high enough to prevent the toes of the affected side from touching the ground, and the sole should be covered with leather to avoid noise when walking.

Here are brief notes of the cases taken from the records of the Orthopædic Infirmary. The first case is that of Henry S., and the record was made by Dr. A. R. Paine.

He is five years old, and was brought to the dispensary for treatment Feb. 4, 1879. His mother states that he began to have trouble in his left hip-joint eight months previously; that he had had pain in the hip and also in the knee from that time to the present, increasing at night; and that for some time he had not been able to walk. An examination revealed the existence of well-marked morbus coxarius, as indicated by the following symptoms: considerable fulness in the gluteal region, obliteration of the gluteal fold,

the thigh slightly flexed upon the body; there is apparent ankylosis at the hip-joint, the pelvis moving with the femur; the effort to move the joint produces great pain; there is also pain on pressing the trochanter inward and when the foot is jarred. The elevated shoe and crutches were ordered for him.

He was seen a second time Feb. 21st. Has used the shoe and crutches about a week. The first day he tried them he was run against and knocked down, falling of course upon the lame hip; he suffered a

FIG. 1.

FIG. 2.—Shows the shoe alone.

great deal from the injury, cried all night, and the flexion of the limb was greatly increased, but on getting upon his crutches in the morning the pain subsided and the limb gradually resumed its former position. Since that time he has had much less pain and goes about easily and comfortably. March 11th, the mother says the boy is doing "splendidly;" he has no pain day or night, and the position of the limb is good. The case is before you, and speaks for itself. There is every reason to suppose that it will progress satisfactorily.

CASE II.—Morbus coxarius (third stage); progressive improvement by the use of the elevated shoe and crutches.

This little boy, three years old, was brought to the Orthopædic Infirmary, Feb. 14, 1879, and the record of his case was made by Dr. H. W. Rand.

The parents think the present trouble commenced when the child was six months old. He is tolerably well nourished, and gives no history of injury. When he began to creep it was noticed that he favored the right leg. Two months later swelling appeared around the hip-joint, most prominent in the groin, where it was opened by the family physician, discharging a thin yellowish fluid.

Since the child began to walk he has always borne the most weight on the ball of the foot, rarely allowing the heel to touch the floor, owing to flexion of the thigh on the trunk. He complained of very little pain until December of last year, since which time

pain has been almost constant and referred to the hip-joint.

When presented at the infirmary, the thigh was flexed on the abdomen, foot inverted, pelvis drawn up on the affected side, nates flattened, and gluteo-femoral crease lowered. Movement of the thigh excited spasmodic action in all the muscles around the joint, producing apparent ankylosis of the hip-joint, the pelvis moving with the femur. Pressure of the head of the femur against the acetabulum and pressure behind the trochanter caused pain.

Ordered elevated shoe (2½ inches) for left foot, and crutches.

Patient returned March 4th. Has learned to walk with the crutches and has had no pain for the past week. When last seen—March 11th—he was still entirely free from pain. Movement excited less spasmodic action in the muscles around the joint, and the flexion of the thigh on the abdomen had somewhat diminished.

A point of interest in this case is the early period at which children may be taught to use the elevated shoe and crutches.

The third case I bring forward as an illustration of complete recovery from morbus coxarius (third stage), treated by the elevated shoe and crutches. This case has been fully reported in the January No., 1879, of *Hays' Journal*, from notes by Dr. Paine, and I will not repeat it here. An examination shows that the position of the limb and foot is perfectly normal; there is no shortening; the joint moves freely in all directions without pain; the most careful scrutiny reveals no evidence of disease, and he looks and feels well. He was under treatment at the infirmary for eight months, when his recovery was pronounced complete.

By the simple appliances shown upon the patients whom I have presented to you this evening we fulfill all the indications for the mechanical treatment of hip-joint disease, and I desire to emphasize the statement that whatever artificial appliances for fixation and extension may be added, they simply tend to increase the discomfort of the patient.

Immobility, which is just as important to obtain in the treatment of inflammation of this as of other joints, is secured by reflex contraction of the peri-articular muscles, aided by intra-capsular effusion, and the voluntary effort of the patient to keep the joint at rest on account of the pain which motion produces. Fixation of the joint is one of the earliest and most characteristic conditions in morbus coxarius; and it is so marked, that when we move the limb, the pelvis moves with it; there is apparent ankylosis. This rigidity continues until nature says immobility is no longer necessary; but so long as it is necessary, she secures it better than we can by any artificial appliances. In the later stages of the disease motion is desirable, and gradually, as the inflammation subsides, the muscles become relaxed, motion returns, and ankylosis is prevented, except in extensive destruction of the joint surfaces, in which case a cure by ankylosis is the thing to be desired.

Extension is made by the weight of the suspended limb, which is equal in weight to one-fifth of the whole body, is greater than the weight ordinarily employed for extension, and is quite sufficient to subdue the spasm of the muscles which crowd the head of the bone into the inflamed acetabulum and is the chief cause of the pain which the patient experiences. We all know how promptly contraction of the muscles of the extremities, in cases of cholera or from other causes, is overcome by forcible extension. The pain in the part is relieved not by separating the inflamed ar-

ticular surfaces as has been claimed, for we cannot separate them to an appreciable extent by any amount of extension that can be applied. The extension not only relieves pain, but it corrects the *malposition* of the limb, whatever it may be, and prevents the deformity which would otherwise occur from contraction of the muscles or partial dislocation of the head of the bone. By means of the elevated shoe and crutches *the weight of the body is removed from the diseased joint and the patient can enjoy all the benefits of open-air exercise*, conditions so evidently necessary as to require no special consideration.

It seems to me probable that the method of extension here described is both more efficient and more agreeable to the parts concerned, by reason of being more gradual, equable, less arbitrary and constraining, and, therefore, exciting a less degree of reflex resistance than most other methods. There is a certain degree of instinctive, unconscious recoil in the mind of every patient, young or old, against all the various devices of constraint or imprisonment which a splint or apparatus implies.

This plan of treatment should be adopted at once, whatever the stage of the disease, and continued until the cure is completed, except in the comparatively rare form of arthritic coxalgia, where acute inflammation of the synovial membrane and other soft structures of the joint is suddenly developed, attended with great constitutional disturbance and excruciating pain, increased by the slightest movement of the limb or the shaking of the bed. In such cases it would be inappropriate at first. Until after the acute symptoms have subsided they should be treated in bed with the long splint and the weight and pulley, together with other appropriate remedies.

There may be cases in which it will be necessary to make extension at night, by the weight and pulley, to relieve the usual nocturnal pain, while the elevated shoe and crutches are used during the day, but I have not thus far met with any, even among those who had used the night extension, with some portable apparatus during the day, up to the time they came under my treatment.

The patient soon learns that relief from pain is obtained by suspending the diseased limb, and then he is glad to walk or stand on the crutches three or four hours daily. This appears to be sufficient to relax the muscles to such a degree that spasmodic contraction, with the accompanying pain, does not take place at night.

For children who are too young, and older persons who are too feeble to use common crutches, Darrach's wheeled crutch, or the ordinary go-cart, are admirable aids to locomotion. Darrach's crutch is the best, as it is so constructed that the patient may be partially suspended in the crutch, if necessary; by a perineal band, which prevents fatigue, and it is also lighter and more elegant in construction. The elevated shoe should be used with either instrument. If a case comes under treatment at so advanced a stage that resection is necessary, the elevated shoe and crutches should be used after the active symptoms following the operation have subsided, instead of adopting the usual practice of confining the patient to bed and using the weight and pulley.

THE KNEE-JOINT.

From the diseases of the hip-joint we will descend to those of the knee; but we must take the metaphor in an anatomical, not a surgical sense; for the frequency with which inflammation occurs in the knee-joint, owing to its complicated mechanical machinery

and its exposed position both in relation to atmospheric changes and liability to injury from violence, invests the subject with an interest to the surgeon quite as great, if not greater, than that which pertains to the hip-joint.

For the morbid conditions of the knee-joint the indications for treatment are in all respects the same as for inflammation of the hip-joint, with the addition of *compression* over the joint.

The knee is not, like the hip, surrounded by powerful muscles, which by their rigidity immobilize the diseased hip-joint. It is necessary, therefore, in the case of the knee, to bring to our aid some mechanical restraint in order to effect complete rest. To secure *fixation* of the knee-joint, I use splints made of hatter's felt, such as you see on the patient before you (Fig. 3).

The knee is not, like the hip, surrounded by powerful muscles, which by their rigidity immobilize the diseased hip-joint. It is necessary, therefore, in the case of the knee, to bring to our aid some mechanical restraint in order to effect complete rest. To secure *fixation* of the knee-joint, I use splints made of hatter's felt, such as you see on the patient before you (Fig. 3). It consists of seven layers of cotton-cloth saturated with shellac, and well rolled together while hot. It is manufactured of this thickness specially for me, by Mr. Holley, of South Fifth Avenue, New York, and may be obtained from Tiemann, and I suppose other surgical-instrument makers. That ordinarily sold consists of but five layers of cloth, which for most cases is not firm enough. To give effectual rest to the joint, the splint should be of sufficient length, and wide enough to nearly surround the limb; it should extend half way up the thigh, and to a corresponding point below the knee. A shorter splint, merely wide enough to cover the posterior part of the limb, does not secure the complete immobility which I have insisted upon in the treatment of diseases of the joints, where absolute rest is demanded. The splint having been cut of the proper length and width (the material is easily cut with a sharp knife), and the limb covered with a stocking, the felt made pliable, preferably

FIG. 3.

by dry heat in an oven or before an open fire, or by immersion in very hot water, is applied to the limb and covered quickly, and firmly with a bandage from below upwards, so as to mould it to all the inequalities of the surface. While the splint is being applied an assistant should make extension from the foot, so as to straighten the limb as much as possible in cases where the joint is flexed; but no violent effort should be made to reduce the malposition; this can usually be accomplished by the gradual, painless (physiological) extension made by the weight of the limb, to which we shall presently refer. The joint surfaces are morbidly sensitive to pain, which would be greatly increased if they were suddenly and forcibly pressed together in the effort to reduce the deformity at once. If the surgeon's hands are very sensitive to heat, he may handle the splint better by wearing a pair of cotton gloves wet in tepid or moderately cold water. So soon as the splint regains its inflexibility, and this it does very quickly, it may be removed, trimmed up, and holes punched an inch or an inch and a half from the front edges for lacings. The object in punching the holes a little way back from the edges is to permit the splint to be made smaller by cutting off the edges, so that pressure may be kept up as the knee diminishes in size. The splint should nearly meet in front, and be laced as tightly as the patient can bear with comfort; all the benefits of elastic pressure may be secured

by surrounding the knee with a layer of wool-wadding, which never becomes matted, never loses its elasticity, and is an extremely comfortable method of making pressure, if the patient should complain of discomfort from the splint. If in any case it is considered desirable to leave the top of the knee uncovered, a semi-circular piece may be removed from either side of the splint, and windows may be cut at any point where there are fistulous openings which require dressing. The splint may be made more comfortable in warm weather by perforating it here and there with a punch. If the leg is rotated on its longitudinal axis with a tendency to inversion or eversion of the foot, this should be prevented by extending the splint down to the foot.

If the leg is flexed when the splint is first applied, and cannot easily be forced into a straight position, the angle of the splint should be changed from time to time, as the leg becomes straighter under the influence of extension by its own weight. This may be done by softening the posterior part of the splint by the application of a sponge dipped in hot water; a bandage should then be firmly applied, while extension is made upon the leg by the hands of an assistant. So soon as the splint hardens, the bandage is removed and the lacings tightened. The splint, although firmly applied, does not interfere with the straightening of the joint by the extension made by the weight of the leg.

I prefer the felt splint to one made of plaster-of-Paris, leather, or liquid glass, because, while it is equally firm, it is also lighter, adapts itself just as well to the inequalities of surface about the knee, is more easily applied, its angle may be changed without removing it from the knee, and it may be unlaced and opened to examine the parts, or even removed, without disturbing the joint.

By means of the knee-splint we not only fix the joint and contribute to correct its malposition, but we also make *compression* upon the part, which is a valuable therapeutic auxiliary in the management of these cases, and its importance must not be overlooked. Compression causes absorption of non-purulent effusions into the joint, removes the boggy, infiltrated condition of the connective tissue which surrounds it, protects the part and gives support to the relaxed ligaments and synovial membrane.

Extension is best accomplished by the use of the elevated shoe and crutches which have already been described in considering the treatment of hip-joint disease. (Fig. 1.) The weight of the suspended leg, which may be estimated as one-twelfth to one-tenth of the weight of the body (eight to ten pounds in a body weighing one hundred pounds), is quite sufficient to tire out the muscles, which by reflex contraction compress the already suffering tissues within the joint, increasing the pain and leading to interstitial absorption—in short, the muscles are restored to their length. By means of extension we also correct the malposition of the limb, which is usually contracted to an angle of 120° ; but extension has not the slightest influence in separating the diseased articular surfaces, nor do I consider this necessary. This method of extension is so gradual and equable, and therefore so agreeable to the parts concerned, that the muscles are persuaded to relax, if such an expression is permissible in this connection, instead of being irritated and stimulated to contraction.

The apparatus of Prof. Sayre for producing extension of the diseased knee-joint, as well as the appliances of H. G. Davis and Sherman, of Chicago, for the same purpose, are creditable to the inventive genius

of their respective authors; but those of you who have used either of them must be aware of the skill and experience necessary to apply them properly, the constant attention they require to keep them suitably adjusted, and the discomfort to the patient produced by the irritating effects of the adhesive plaster by which they are attached to the limb. Moreover, the effort to produce forcible extension by these various devices excites reflex resistance, and the patient, young or old, instinctively recoils from the attempt to overcome muscular contraction by an exertion of strength applied by means of an apparatus.

The weight of the body being removed from the diseased joint by the use of the elevated shoe and crutches, the patient should be kept out of doors as much as practicable, and if old enough to understand the rationale of the treatment, the importance of using the crutches three or four hours daily should be explained to him, and, if necessary, their employment enforced. Patients should also understand the importance of keeping the joint at rest. They not infrequently complain of the restraint of the splint, and secretly remove it themselves (I speak especially of dispensary patients), not because they really suffer pain from the position or confinement of the limb, but because they are afraid of losing the use of the joint. I mention this, not to induce you to shut your ears or disregard the complaints of patients—on the contrary, I think they always deserve attention—but to warn you against deceit from this cause.

There are many mild cases of chronic inflammation of the knee-joint characterized by slight effusion into the joint and tenderness on pressure over the lower part of the inner condyle of the femur, or at the inside of the head of the tibia, in which there is no pain on pressing the articular surfaces together. In such cases the application of the knee-splint is sufficient to effect a cure without the use of the elevated shoe and crutches.

When the disease has resulted in destruction of the joint and caries, either from the violence of the attack or the advanced stage of the disease when it came under observation, we may still hope to save the limb and secure a cure by ankylosis. In fact, by rightly carrying out the indications above referred to, of which the first in importance in all joint inflammations is perfect immobility of the part, the most unpromising cases not infrequently recover; but if the patient is becoming exhausted by suppuration and there is not sufficient reparative power left to throw off the disease, resection or amputation may become necessary.

THE ANKLE-JOINT.

In the treatment of inflammation of the ankle-joint and its consequences, *perfect rest* of the parts (mechanical immobilization), and the *removal of pressure* from the diseased articular surfaces, is quite as important, and I may add quite as satisfactory as in the diseases of the hip and knee, and the indications may be met in the same way. Instead of the felt, I prefer to use for fixing the ankle, two splints made of plaster-of-Paris, because they adapt themselves better to the inequalities of the surface about this joint, one to be applied in front and the other behind, extending from the middle of the leg to the ends of the metatarsal bones, and wide enough to leave an interval of half an inch between the edges on the inner and outer side. The splint should be made of two thicknesses of Canton flannel with coarse meshes, or three thicknesses of coarse towelling cut of the proper length and width. One layer of cloth is laid upon a table and covered

with liquid plaster of the consistence of cream, and spread smoothly with a table-knife. The other layers are then immersed in the plaster and applied evenly and smoothly over the first; and when both splints have been prepared, one is applied in front and the other behind, with the under surface of the first layer, which is not covered with plaster, next to the skin, and covered with a roller bandage firmly applied from below upward. The surgeon should now grasp the foot, and holding it at a right angle to the leg, make extension until the plaster hardens, which requires about five minutes. The bandage should then be removed and the splints surrounded by three or four strips of adhesive plaster, and the bandage re-applied more loosely. Windows may be cut in the plaster so as to allow any openings that may exist in the parts to be uncovered. (Fig. 4.)

FIG. 4.

In all cases of diseased ankle-joint, the heel is raised more or less by the contraction of the gastrocnemii, and the toes pointed downward, if it is permitted to pursue its own course, and it is important to overcome the contraction of the muscles and place the joint at rest with the foot in its normal relation to the leg, (1) to secure its proper position, should ankylosis take place; and (2) to relieve the pain produced by the unremitting muscular contraction day and night.

To remove pressure from an inflamed ankle-joint, and to provide means for letting the patient get the benefits of the open air, is not less important than in the case of a diseased hip- or knee-joint. To accomplish these essential indications, a variety of instruments have been devised; but they are liable to the same objections which have been found to the appliances used for producing extension of the knee-joint. After an experience somewhat extended in the treatment of these affections, I have no hesitation in recommending the elevated shoe and crutches as the best and simplest method of making extension and removing pressure; it is just as effectual for the ankles as for the knee- and hip-joints. The weight required is not great, and the weight of the foot is sufficient to overcome the muscular contraction.

If the foot, from long neglect, cannot at once be brought to a right angle with the leg, the splints should be renewed every five or six days, increasing

the extension a little at each application, until the foot is brought into proper relations with the leg.

The advantages which the mechanical treatment here described possesses over that commonly employed in the management of the diseases of the lower extremities are:

1. It saves the surgeon the trouble and annoyance of applying and carefully watching the instruments in ordinary use, to see that proper extension is kept up and undue pressure prevented; while the patient's comfort is greatly promoted by dispensing with adhesive plasters, which irritate the skin and require removal from time to time, and also with the perineal band in hip disease, which is a constant source of discomfort.

2. The spasmodic contraction of the peri-articular muscles is overcome by the gentle, persuasive, and painless (physiological) extension made by the weight of the limb for several hours each day; whilst forcible extension, either by the ordinary portable instruments, or by the weight and pulley, irritates the muscles and stimulates them to resistance and contraction, which must be overcome by main force.

3. I am quite confident, judging from the experience thus far obtained, that the plan of managing diseases of the joints herein described will shorten their duration more decidedly than can be done by the older methods of treatment.

4. The apparatus (if so simple a thing deserves the name of apparatus), is inexpensive, and can be made by any ordinary mechanic.

In conclusion, Mr. President, allow me to say that it was with a good deal of reluctance that I ventured to condemn as useless or hurtful the appliances hitherto in use in the treatment of diseases of the hip-, knee-, and ankle-joints, and to commend to professional notice new and simpler methods. I should not have had the audacity to do so, had not my convictions, based upon practical experience, have seemed so plainly to warrant the positions I have endeavored herein to maintain. These convictions have been strengthened also by the favorable opinions expressed of the treatment of hip-joint disease, since the publication of my paper upon the subject, by surgeons in different parts of the country, for whose judgment I have long been accustomed to entertain the highest respect.

Progress of Medical Science.

CASE OF ATHETOSIS—DEATH FROM PHTHISIS—POST-MORTEM EXAMINATION.—H. B., æt. thirty-three, was admitted January, 1877, to Westminster Hospital in an advanced stage of phtthisis. When the patient was three years old he had whooping-cough, and soon after two fits, which left him paralyzed on the left side. He gradually gained power, however, in the limb, and at the age of ten could run about as well as other boys. The athetosis appeared soon after the fits, and gradually increased in severity as power was restored. The inco-ordinated movements had not changed much during the past twenty years.

The movements were almost exclusively confined to the left upper limb, and were continuous and involuntary. When the hand was extended with the palm downward, the index and middle fingers were slowly and gradually flexed. The thumb was also adducted, the hand was then supinated, the fingers again extended and the thumb abducted. Pronation of the hand completed the cycle. This type of movement was, however, subject to some variation. When the fingers were flexed it required considerable force to extend them. Patient could slightly control the movements by a great effort of the will. The hand was only quiet during sleep; the movements were so constant that the patient could not use the hand for any of the ordinary purposes of lifting. The left leg occasionally exhibited a somewhat similar condition, but only when he was tired out after a long walk. The movements were increased by worry and trouble, and appeared to be diminished by smoking. There was no loss of sensation in either hand. The muscles on the posterior aspect of the forearm were much more wasted than those on the anterior aspect. The patient died from diarrhœa and exhaustion on March 19, 1879.

Autopsy.—Brain: right hemisphere distinctly smaller than the left, about three-quarters of an inch shorter; the posterior half of the middle and inferior frontal convolutions, and, to a slighter extent, the superior and ascending frontal, were distinctly smaller on the right side than on the left; the right parietal convolutions were also smaller on the right side. There was a depression on the anterior portion of the temporo-sphenoidal lobe, about one inch long. There was a deep depression extending backward into the lobe, about three-quarters of an inch deep. The right anterior pyramid was very conspicuously smaller than the left. The convolutions of the island of Reil were apparently normal, but, on the inner side, a deep excavation was found between the anterior extremity of the perforated spot and the convolutions, extending backward to the level of the corpora albicantia, and forward, between the convolutions of the island of Reil and operculum, to the anterior surface of the hemisphere. Anteriorly the fissure was three-quarters of an inch deep, and about two-and-a-half inches long. The sides seemed to have been in apposition except outside the perforated spot, where the cavity was about one-fourth inch wide; its roof was formed by radiating fibres spreading upward from the pons. Upon opening the ventricles, almost the whole of that portion of the right corpus striatum lying in front of the thalamus appeared to be destroyed; posterior portion of nucleus caudatus unaffected. A small portion of the inner part of the corpus striatum near the middle appeared intact, but the

INJURY OF THE EYE INFLICTED BY THE BEAK OF AN OWL.—M. Dufaur reports the following interesting case: A common brown owl had built its nest beneath the projecting roof of a farm-house, where it had a brood of young ones. One day the farmer, moved by curiosity, drove away the old bird, took out the young owls, and, after looking at them, replaced them uninjured in the nest. In the evening, as he was entering the house with his servant, the latter suddenly heard the beating of wings, felt the claws of the owl on his chin, and before he could defend himself, received a blow from its beak directly under the eye. Fortunately the sight was not affected, and the man escaped with some severe pains. On the following day an unsuccessful hunt for the bird was instituted, but in the dusk of the evening it appeared again, and attacked the farmer himself, striking him directly in the eye with its beak. M. Dufaur was consulted, and found a wound of the cornea, one and a half centimetre in length, and an abundant intraocular hemorrhage. The sight of the eye was completely lost, and the other eye was subsequently threatened with sympathetic inflammation. — *Le Mouvement Médical.*

whole of the gray substance was destroyed. The optic thalamus seemed to be quite healthy.—*The Lancet*, Dr. Sturges, March 15, 1879.

THE USE OF THE ACTUAL CAUTERY IN MEDICINE.—In choosing a cautery, it is always advisable to select one with a platinum tip, since this metal will not become rough from long usage. The Paquelin benzine cautery is the most serviceable one hitherto invented, the only objection being its great cost. The Brown-Séquard cautery (which merely consists of an olive-pointed steel cautery-iron about 30 cms. long, the olive being about 15 mm. in diameter at the base, and carefully covered with platinum), will, however, answer all practical purposes. This may be heated to a white heat in a grate-fire.

The method of application usually adopted is that called "cautérisation transcurrente" by Jobert and Notta, which consists in making very light parallel strokes with the cautery at white-heat over the part chosen as the seat of counter-irritation. From four to twelve strokes can be made in a very short space of time, and with very little suffering; only the cuticle should be affected in order to avoid subsequent suppuration. One error to be avoided is striking hard at the beginning of the strokes, since this causes blistering and suppuration. The only dressing required is the application of a piece of linen. It is often desirable to repeat the cauterization frequently. In spinal affections we may begin at the top and cauterize the entire spinal region systematically and repeatedly by means of daily or tri-weekly applications. The majority of patients consider the pain very slight. It is highly unphysiological to freeze the skin previous to the application of the cautery. Superficial cauterization with the actual platinum cautery has been satisfactorily used in the following conditions:

1. Neuralgia, acute and chronic, of the trigeminus and of the peripheral nerves.
2. Spinal irritation and various cerebral paræsthesiæ (pressure, numbness, etc.).
3. Spinal congestion.
4. Various forms of myelitis, acute and subacute.
5. Epilepsy (not by myself).
6. Intercostal pain.
7. Lumbago, acute and chronic.
8. Articular inflammation.
9. Peri-arthritis (chronic rheumatism?) especially of the shoulder.—*Archives of Medicine*, Dr. E. C. Seguin, April, 1879.

A CASE OF OBSTINATE ULCERATION OF THE NECK OF THE UTERUS CURED BY GRAFTING.—The patient was a prostitute who had been previously treated for pelvic peritonitis. Examination with the speculum showed that the neck of the uterus was very much enlarged and hard, and around the os was a circular ulcer seven-eighths of an inch in diameter, and longer in the vertical direction; its surface was studded with bright red, healthy granulations. The ulceration was treated in a variety of ways for one and a half months without producing the slightest benefit. Grafting of mucous membrane was then resorted to in the following manner: A small fold of mucous membrane was stripped off from the side of the vaginal wall, and was cut in two. The granulations on the ulcer having been scratched below and to the left of the os, the pieces were embedded in the granulations by means of an instrument used for tying deep sutures. Another piece of membrane was cut off and embedded in the granulations above the os. The speculum was left in position, and the patient kept on her back for an hour, at the end of which time a large tampon of

cotton, moistened with pure glycerine, was placed against the ulcer, and the speculum was withdrawn. Strict quiet in bed was enjoined, and the tampon was removed the next morning. Five days afterward a pellicle of newly-formed mucous membrane was found to have formed from the three grafts. The remainder of the ulcer retained its red granular appearance. Three days later, the ulcer was all covered with new mucous membrane, except a narrow rim just above the external os. A fresh piece of vaginal mucous membrane was now placed in each external angle of the os and treated in the same manner as previously. When examined, a month later, the site of the ulcer was entirely covered by new mucous membrane.—*Archives of Medicine*, Dr. R. W. Amidon, April, 1879.

SUPPLEMENTARY RECTAL ALIMENTATION.—Rectal alimentation is indicated when there is an obstacle to the introduction of food into the stomach, or to its passage beyond the stomach; or when there is inflammation or ulceration of the stomach, causing ejection of the food; or when there is reflex vomiting to an extent sufficient to imperil life. It is also indicated in the condition known as *weak stomach*, which is usually the result of poverty of blood, due to hemorrhages, protracted suppuration, scrofula, phthisis, renal disease, etc. Insufficient nutrition forms an important factor in almost all these chronic diseases, and the use of rectal alimentation to supplement alimentation by the stomach furnishes a valuable addition to our resources in such cases. Various articles have been used, such as milk, raw eggs, animal broths, Leube's preparation of meat. Dr. Smith obtained much more valuable results from the use of defibrinated blood. In urgent cases, especially when the stomach cannot be called upon to perform its office at all, 30 to 90 grms. of defibrinated blood may be injected into the rectum every two or three hours. For chronic cases, in which it is merely given to aid stomach nutrition, 90 to 180 grms. may be given once or twice a day. An ordinary syringe may be employed, care being taken to cleanse it thoroughly after each injection. If the rectum is irritable, the blood should be gently warmed to the temperature of the body. Dr. Smith employed this measure in eighty cases. In two or three cases the rectum became so irritable that the injection was immediately voided; in about one-third of the cases more or less constipation occurred; in two cases the discharges were very offensive; in one case nervous irritability and insomnia were produced. Otherwise, the use of the blood was not attended by any ill-effects. About forty of the patients treated by Dr. Smith suffered from pulmonary phthisis. Marked benefit was obtained in about one-half of these cases, although nearly all had been previously treated with cod-liver oil, stimulants, tonics, quinine, etc. Quite a number of cases of simple anemia were treated with excellent results in all, with the exception of one patient, who was suspected to be suffering from congenital arterial hypoplasia. The treatment was also found to work admirably in atonic dyspepsia, dyspeptic asthma, inveterate neuralgia, nervous exhaustion, etc.—*Archives of Medicine*, Dr. A. H. Smith, April, 1879.

SIX DAYS BURIED IN A MINE.—Seven men were entombed six days in a Wilkesbarre coal-mine last week, and were rescued, alive and well, through a shaft which had to be sunk 1,200 feet for their relief. They subsisted on the flesh of a mule, which "agreed" with all but one, whom it caused to have diarrhœa. They had a good supply of air and water.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

INSANE ASYLUM REFORMS.

THE appointment of a staff of attending physicians to the Hudson River State Hospital for the Insane, at Poughkeepsie, N. Y., is an innovation in asylum management which promises much good. On general principles we have maintained that the medical staff of our insane asylums is too small for the work that is expected of them. As a rule, the superintendent is the only person of the staff whose reputation and experience entitle him to the position as an expert and medical adviser for the insane. Strange as it may seem, he is the only one who does not see the patients regularly, that duty being left to his assistants, one or two in number, who are supposed to make regular visits daily. The function of the medical superintendent is more that of an architect, civil engineer, business manager, and farmer, than a practised clinician. This is the fault of our asylum organization, which considers hospital construction and everything pertaining thereto of paramount importance in the care and treatment of the insane. In order to meet all the requirements of what is understood as the duties of medical superintendent, the medical care of the patients must be more or less neglected. The cases are treated by wholesale, or left entirely to the assistants—the latter, as a rule, being young and inexperienced, and altogether too few in number to study the cases profitably.

As we understand the new plan as applied to the institution at Poughkeepsie, it is similar to that of general hospitals, with the exception perhaps that the chief executive officer is a medical man. This arrangement would place the organization of the hospital on a similar footing with the United States general hospitals which were in existence during the war, while an independent attending staff will give the institution all the clinical advantages of a metropolitan hospital.

Another benefit which the change will confer upon

medical science will be a more thorough clinical study of insanity, by introducing new views, by instituting new methods of treatment, and by distributing the work among many workers, and thus enlarging the field of observation. Not the least of the advantages which may be gained by the new arrangement is the opportunity which may be given to the average medical student of studying insanity in the wards of an asylum, and of listening to clinical lectures upon the same by his professor. Of course, in regard to this point we can only speak in a general way, presuming that the change in the Poughkeepsie asylum may be adopted in institutions nearer home and more accessible to students. The attending staff of the asylum in question is unexceptionably good, made up of representative men, who will, no doubt, take every advantage of the situation, and solve, if possible, one of the most important problems of asylum management.

MEDICAL REFORM IN GREAT BRITAIN.

THE demand for reform in medical education and kindred matters, although not so urgent as with us, is by no means confined to this country. The centralized and too paternal methods practised in France, which give to the University of Paris a monopoly of medical education, began some time ago to excite much complaint there; and this has lately resulted in giving some meagre privileges to the provinces. In England there are just now several reformatory measures on foot, the adoption of which is being attempted by the profession. It may be remembered that in Great Britain the state has very little to do with the regulation of medicine. It attempts only to furnish an authentic list of qualified practitioners, and to define the minimum of qualification which will entitle a physician to be put upon this general register. These two things it does through the agency of a General Medical Council—a body consisting of twenty-four persons, selected partly by the crown, but chiefly from the large universities and the medical colleges. There are nineteen medical corporations in Great Britain which can license a person to practise. These corporations all compete with each other for students; and their requirements for a degree or license, although there is a prescribed minimum, vary much with the different institutions. So that practically it is a quite notorious fact that, if a student is apprehensive of failure before one examining board, he will slip off to another which gives easier terms. In order to remedy this evil, it is proposed that there be a conjoint board of examiners, made up from the various medical schools, and that this board be empowered to examine and give licenses to those whose qualifications are found to exceed a certain minimum. There are further details which complicate the matter, but into which we need not enter. The project has this advantage, that the minimum qualification cannot be a very

high one, certainly not so high as that already adopted by some of the best schools, although higher than that of the poorer ones. The conjoint board scheme, however is, on the whole, pretty generally approved by the medical press and public.

A second trouble which disturbs the British mind is the composition of the General Medical Council. This now represents chiefly the medical colleges rather than the profession at large, and it is accused of being a corporation organ, a partisan and inefficient body. It is very strongly urged that there be a direct representation of the profession among its members, and the proposal is no more than reasonable. But the Medical Council has recently voted that things are best as they now exist, and the profession at large is not strong enough in Parliament to get a law passed changing the composition of the body in opposition to its influence and vote of self-approval. There is a feeling against it, however, which will undoubtedly result in securing the desired change in course of time.

A third project of reform is one in regard to quacks and impostors. There is now practically no law against such parties, and some legislation is sought by which they may be suppressed. However desirable such a measure might be, it is not likely that any remedy will be obtained during the present session of Parliament, so that the herb-doctors, dynamic physicians, and specialty men are likely to continue flourishing for a time longer. It may be some satisfaction to Illinois to know that it is ahead of England in this respect.

In regard more particularly to medical education, there is frequent complaint that the students are deficient in preliminary qualifications, and that the course of instruction is not long enough. Although there exist regulations requiring a certain amount of general education before matriculation, we imagine that, like similar requirements in this country, they do not amount to much, and the idea of a prospective student being rejected on account of deficiencies in this particular is never seriously entertained. This higher preliminary education is one of the things which is universally agreed to be very desirable, and in this pleasing unanimity the matter rests, while blockheads continue to matriculate and take out tickets at the regular rates. And so it will continue in England, as with us, for a long time to come.

The course of study covers forty-five months, of which thirty must be spent at a medical college, and, during the time, two examinations be passed. The project of extending this course from four years to five, as in Germany, or to six, as in Italy, is one that has been strongly urged, but firmly and successfully opposed; and if the English system were like ours we should be inclined to doubt its advisability. For four years spent in hanging over text-books and sitting through didactic and clinical lectures, things

which make up the American students' education, would be quite as much as the average mind could tolerate. The facts thus accumulated would need to be vivified by experience and practical work among the sick and injured. Under the English system, however, such practical applications of theoretical knowledge are being constantly made to a greater or less extent. Every student is obliged to act as ward clerk, assistant dresser, or in some similar position, sufficiently unpretentious but undoubtedly useful in bringing him into direct contact, medically and surgically, with disease. Five years of this kind of study, therefore, might be valuable, as it seems actually to be in Germany. But it would be necessary for us to change our "system" as well as lengthen our course. Indeed, the idea of the American student ever being obliged to devote himself to five years of useful and practical study is beyond the dreams of the most hopeful optimism.

It may be a useful, though a somewhat melancholy task, to contrast the deficiencies, often enough harped upon, among us, with the comparatively trivial ones about which the British medical profession is agitating itself.

The latter asserts that it needs a change in the composition of the General Medical Council, the establishment of conjoint examining boards, legislation against quacks, and a higher preliminary education.

Our deficiencies, as summed up by Dr. Pepper, are: a strict examination preliminary to matriculation; personal training in the practical branches; a regular grading of the curriculum; an examination for candidates for degree by those not pecuniarily interested in the success of the candidates. And we can add that we also need protection against quacks and impostors as well as against those numerous diploma mills and corporate advertising bodies which exist under the name of medical colleges.

SALICYLATE OF SODA IN GOUT.—In a letter published in the *Jour. de Méd. et de Chir.*, a physician of forty years' standing gives his personal testimony to the value of salicylate of soda in gout. He had been subject for twenty years to attacks of gout, rheumatism, and sciatica, which came on several times every year, and were sometimes exceedingly violent. His urine was very often loaded with uric acid, and several of the joints of his feet and hands were immovable from gouty concretions. He began the use of salicylate of soda in August, 1877, and has continued it ever since, without a single day's interval. Since then he has had no attack either of the gout, the rheumatism, or the sciatica, and his urine has never presented the brick-dust deposit so often observed previously. His joints also have regained a certain degree of mobility. He takes 15 grains of the salt with each meal, except in the heat of summer, when he reduces the dose to 30 grains per diem. He drinks about a quart of wine a day, but dilutes it with carbonic acid water, to which 30 to 45 grains of bicarbonate of soda are added.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting April, 9, 1879.

DR. J. W. HOWE, VICE-PRESIDENT, IN THE CHAIR.

AMPUTATION OF THIGH FOR KNEE-JOINT DISEASE.

DR. WYETH presented a specimen of disease of the knee-joint removed by amputation of the thigh, from a boy aged ten years. He saw the patient for the first time in 1876, when there was present a severe inflammation of the knee-joint with flexion of the leg. An extension apparatus was applied with the effect of strengthening the limb, and at the end of a few months afterward the patient was able to walk. Unfortunately he received an injury from a fall, when the old trouble in the knee revived and increased until there was disorganization of the joint and its surroundings, with extensive infiltration into the neighboring muscles. All hope of saving the joint having been given up, amputation was decided upon. In order to make the section through sound tissue, the amputation was made in the middle third of the thigh. Dr. Wyeth thought that the latter was the better course, inasmuch as the suppuration was very profuse and the child was not in a condition to tolerate much subsequent discharge from the stump. In conclusion, he exhibited the joint, which showed osteitis of the condyles of the femur, erosion of the articular cartilages, and a pulpy condition of the synovial membrane, with fibrinous exudation of the capsule. He wished to know whether or no the disease commenced in the synovial membrane.

AMPUTATION THROUGH INFLAMED AND INFILTRATED TISSUES.

DR. SHRADY thought that the disease originated in an osteitis. In regard to amputation of the thigh, he believed the rule to save as much of the femur as possible was a good one, even if it were necessary to make the section through soft tissues involved in suppuration. He had performed two weeks previously a supra-condyloid amputation of the thigh for disease of the knee-joint, in which the entire anterior skin-flap was infiltrated with fibrinous exudation and contained numerous sinuses. The flap took on a healthy appearance in a few days, the skin became of a natural color and suppleness, and there was no sloughing at any point.

DR. BRIMON believed that the disease originated in the articular extremities as an osteitis, the joint becoming secondarily involved by erosion of the cartilages and subsequent pulpy degeneration of the synovial sac. He did not think that there was any danger in using, for flaps, skin that was infiltrated or contained sinuses; in fact, the real risk was in making the section of the thigh high enough to clear them. Every inch of the femur which was sacrificed added to the risk of the patient. In every case where there was a choice between using an unsound flap or making a section of the bone higher up to clear it, he should always be in favor of the former. In fact, in the majority of cases these infiltrated flaps do better than the ordinary ones made through sound integument. In his experience the suppuration from the sinuses very soon disappeared.

DR. POSE stated that there was a certain amount of quasi-reparative action in infiltrated flaps which helped

to explain the reason why they healed so kindly. In this connection he referred to the practice of Dieffenbach, who prepared flaps for transplantation by undermining them two or three weeks beforehand. Under the circumstances the capillaries of the part became enlarged, and were better prepared to take on reparative action than when merely healthy tissue was used.

DR. HOWE did not think that the cases were parallel ones. In one healthy skin was raised from the cellular connections for eight or ten days, while in the other inflammatory processes over years had infiltrated the skin with purulent matter, produced ulcers, and in every way made it unfit as a covering for a stump.

OLD PELVIC PERITONITIS; CHRONIC CYSTITIS; URETERITIS AND PYELITIS; PERIURETERITIS; PERINEPHRITIS; CHRONIC INTERSTITIAL NEPHRITIS; LYONEPHROSIS (LEFT); PYEMIC INFARCTIONS OF LEFT LUNG; CROUPOUS PNEUMONIA (RIGHT); CEREBRAL CONGESTION; MITRAL STENOSIS; FATTY HEART.

THE above is a statement of the numerous pathological lesions found at the autopsy of a German woman, 37 years of age, who died under care of Dr. Beverley Robinson, in the Penitentiary Hospital, B. I., on April 5th, at 11.40 P.M. The previous history of this patient is but little known. Prior to her decease she had been in the hospital twenty-six days, and shortly before the date of admission she had had a convulsion. She was suffering from a vesico-vaginal fistula, which allowed her urine to dribble away from her so soon as it entered the bladder. There was marked pain over the epigastrium, loss of appetite, and constipation. She was anæmic and much emaciated. Her temperature was about normal.

A careful examination of the chest gave negative signs (statement taken from ward-book). The condition of the urine was not examined.

I saw the patient for the first and only time on April 5th, about seven hours before she died. At that time I was informed she had taken little nourishment during the past two days, and even that little she had in great part vomited. Patient had been in a state of hebetude all day, and craving water to drink. The pupil of right eye was contracted, the left pupil was covered by a staphyloma. Pulse 96, very feeble, extremities cold, and general temperature sub normal. There was no sensation when a pin was imbedded in the skin of the hands. There was moderate subsultus; tongue dry and coated; respirations shallow, but of normal frequency. Upon a rapid and imperfect physical examination but few physical signs were revealed; still it was thought probable that both lungs were in a condition of hypostatic congestion, rendered obscure by the state of collapse, in which the patient was at the time of my visit. The mental hebetude was presumably due to cerebral œdema; cause unknown. The prognosis was of course pronounced imminently grave.

At the post-mortem interesting lesions were found in the lungs and kidneys, which I here offer to your consideration.

The lower lobe of this right lung, you perceive, is completely consolidated by croupous pneumonia, apparently in the gray stage, and from its surface of section a thick, tenacious, puriform liquid can still be scraped. In other portions of the lung there are evidences of emphysema, œdema, and congestion. The bronchi are inflamed. At the origin of the pulmonary artery is seen a large clot extending itself into its branches. This is not to my eye altogether a thrombus. There appears to be a sort of central spot of different and pinkish coloration, about which the

white fibrin has deposited. Taken in connection with the condition observable in the left lung at the autopsy, this has additional significance. Here there were several large hæmorrhagic infarctions, limited, however, to the lower lobe. In different portions of the entire lung are hard nodules, which present on section "a yellowish white granular surface, from which on pressure a puriform fluid can be squeezed" (pyæmic infarctions).

The entire upper half of left kidney has become an abscess, containing yellowish pus mingled with cheesy material. The remaining portion of the cortical and medullary structure present the lesions of chronic interstitial nephritis. The entrance of the left ureter into the bladder is blocked with a small white calculus. Behind this obstruction a narrowed ureter with thickened coats is seen. The pelvis of left kidney is dilated and its lining membrane much thickened. Bladder is contracted. The mitral orifice of the heart is markedly stenosed.

To microscopical examination the right lung gave the following results: "large quantity of pus cells in the inflammatory exudation, a few epithelial cells, no fibrin, a very few red blood-corpuscles, and an immense number of bacteria. The chief peculiarity about the lung was the large quantity of mucus."

Inasmuch, also, as upon close examination the consolidation was neither strictly lobar nor yet lobular, it was extremely difficult to classify it among the types of croupous or catarrhal pneumonia.*

ENCHONDROMA OF PAROTID REGION.

DR. A. C. POST exhibited an enchondroma which he had removed by operation from the region occupied by the parotid gland. The tumor was exceedingly hard, was firmly attached, and extended down deeply behind the ramus of the lower jaw. Its relations to large cervical vessels was so close, that it was considered prudent to make the chief incisions behind. After working about an hour the tumor was separated sufficiently from its connections to be seized by a vulsellum and turned upon its axis. In so doing the end of the styloid process was snapped off and removed with the growth. Dr. Post believed, notwithstanding that the tumor occupied the locality of the parotid gland, it was not a growth from that organ. His reasons for such a view were that neither the external carotid artery nor the facial nerve were encountered in the operation of extirpation of the tumor.

THE RELATIONS OF THE EXTERNAL CAROTID TO THE PAROTID.

DR. WYETH remarked that it was the rule that the external carotid artery should perforate the parotid, but that rule was by no means absolute. Morton speaks of the external carotid as making only a groove in the gland, and Dwight says that the artery does not enter the gland from below, but on the inner side, at a point which is variable.

DR. POST stated that he once undertook the removal of a tumor, which he had no idea was one of the parotid. He found, however, on coming down upon its deeper surface, that there was a contraction behind the jaw and then an expansion of the growth. Carrying on the dissection further, the external carotid artery and facial nerve were encountered. The patient lived a year afterward, and died of cancer of the internal parts. Dr. P. also alluded in this connection to another case which was similar in regard to the existence of a tumor of the parotid. When he found the latter

to be the case, he concluded not to proceed with the operation. When the patient recovered from the effects of the anæsthetic he was informed that the tumor was not removed, because in so doing the facial nerve would be injured, as well as one of the large arteries of the neck, and that there would be an inability to close the eye of that side, with probable loss of the organ.

PARALYSIS OF FACIAL IN THE REMOVAL OF THE PAROTID GLAND.

DR. BRIDDON stated that within the past six months a tumor of the parotid region was removed at the Presbyterian Hospital. After the removal of the growth, the part that should have been occupied by the parotid was empty, but as neither the external carotid nor the facial nerve were encountered in the dissection, it was concluded that the parotid gland was not involved. Notwithstanding this state of things, the patient suffered from paralysis of the orbicularis palpebrarum, and was consequently unable to close the lid of that side.

DR. SHRADY remarked that the paralysis did not occur until four or five days after the operation, and was probably due to pressure upon the trunk of the nerve, the result of inflammatory processes.

DR. BRIDDON thought that the paralysis did not show itself at first because of œdema of the lids.

BONY ABSCESS IN MIDDLE OF TIBIA.

DR. POST presented a second specimen, which consisted of a disc of the anterior wall of the tibia removed by operation for abscess of that bone. The patient was a boy aged eighteen years. Two years ago he received a contusion of the leg, followed by severe and deep-seated pain. The latter condition existed until two months before the operation, when an inflammatory swelling appeared a little above the middle of the tibia. This swelling went on to suppuration. The abscess was opened, and a probe being passed into it went entirely through the tibia to its posterior wall. Several days afterward the bone was trephined, when a bony cavity, four inches in length in the middle of the tibia, was laid open. The abscess occupied the whole circumference of the medullary cavity and was surrounded by eburnated bony tissue. The interest of the specimen was in the extreme rarity of bony abscess in that locality. A third specimen by Dr. Post consisted of the astragalus and os calcis removed by exsection from a girl aged sixteen years. The patient had suffered for some time with abscess of the ankle-joint, associated with sinuses and rough bone. The principal disease was found to be in the synovial membrane and articular cartilages between the two bones referred to. The disease in the lower portions of the bones of the leg was very slight. The operation was performed by the sub-periosteal method.

TUMORS OF FOREARM.

DR. HOWE presented a tumor of the forearm which he had removed by operation from a patient in the St. Francis Hospital.

The tumor occupied the upper four-fifths of the ulna and involved the periosteum, flexor profundus digitorum, flexor carpi ulnaris, pronator quadratus, ulnar artery and nerve, all of which were removed except their upper and lower attachments. The lower portion of the tumor contained a hard mass resembling bone. The patient was a seamstress, aged 21, of good habits, and without any hereditary disease. The tumor commenced nine years previously at the upper end of the ulna. It gave her no pain, and did not inconvenience her in the least. Three years subsequently a sec-

* This opinion is that of an expert in microscopy.

ond and separate tumor appeared at the wrist-joint. For four weeks the tumor seemed to grow rapidly and give her pain. The fingers were flexed, so that their ends reached the palm of the hand, and she could not extend them. The thumb retained all its power and the index finger was also capable of some considerable movement. The removal of the tumor was performed under Lister.

Dr. Howe stated, in conclusion, that Dr. Shrady, who assisted in the operation, was of the opinion that the tumor was a periosteal sarcoma.

Dr. BRIDSON did not see anything in the specimen which favored such an opinion.

Dr. HOWE was not prepared to say what was the nature of the growth.

Dr. SHRADY remarked that the specimen was much altered in its general appearance since its removal. He stated that he had made a careful examination of the case before the operation, and made the diagnosis of a periosteal sarcoma, which involved the ulna, deep flexors of the forearm and the pronator radii quadratus, extending across the latter muscle and being attached to the radius. The operation proved the diagnosis to be correct as far as the attachments of the tumor were concerned. Except the period of its growth, it presented clinically all the features of a sarcoma. The gross character of the growth, and especially the appearance of osteoid tissue in the substance of the tumor, confirmed such an opinion. He regretted that no microscopical examination of the tumor had been made.

Dr. POST referred, in this connection, to a specimen which had been taken from an old case of hip disease, and in which there was a deposit of bone developed in the midst of the neighboring soft parts, and unconnected with any of the bones of the skeleton.

On motion, the specimen of tumor of parotid region presented by Dr. Post, and of tumor of the forearm, presented by Dr. Howe, were referred to the committee on microscopy.

The Society then went into Executive Session.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 17, 1879.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

CATARACT EXTRACTION, WITH A STATEMENT OF TWO HUNDRED AND FIFTY CASES.

DR. C. R. AGNEW read a valuable and interesting paper, and offered for the consideration of the Academy a tabular statement of two hundred and fifty consecutive cases of cataract extraction, with such comments as seemed to him to be the fruit of the experience which they afforded. One hundred and eighteen of the number had already been published, while one hundred and thirty-two had not heretofore been tabulated. He brought the cases altogether in order that a broader basis might be made for such animadversions and deductions as naturally followed from their consideration. Of course we all desired to know what was the best method for the removal of a hard cataract, and what was the prognosis in such operative interference. In considering the question of cataract extraction it was difficult to generalize, unless we did it upon a basis of a very large number of cases. Ever since von Graefe had given us the method of modified linear extraction, the danger of failure to give improved vision in cataract cases had steadily lessened

whenever ophthalmic surgery was intelligently practised. He thought it might be safely said that the danger of total loss might be stated as being considerably less than *ten* per cent. In the group of 118 cases already published by him the percentage of failure to restore vision was $9\frac{1}{2}$ per cent. In the group of 132 cases the percentage of failure to restore vision was $8\frac{1}{4}$ per cent. Combining the results of the two groups there was a percentage of failure to restore vision of $8\frac{1}{2}$ per cent. Dr. Agnew thought that the more obvious lessons which those cases taught might not be without value as helping to show us what to do or what not to do in our immediate practice. The more experience he had, the more his confidence increased in the comparative value of that method for the removal of hard cataract which was known as *Graefe's modified linear method*. By that he meant the method which consisted essentially in the removal from the eye of the crystalline lens, without its capsule, by making an incision upward in the margin of the cornea, and removing by an iridectomy that opposing portion of the iris which laid in the way of the easy delivery of the lens. In common with most, if not all surgeons, he made a wound, the edge of which extended about a millimetre back from the margin of the clear cornea, while at least three-fifths of its entire extent was distinctly in the clear cornea, but bordering upon its opaque edge. The position of the wound differed decidedly from that which Graefe first selected, and for a most excellent reason that it kept away, throughout the greater portion of its extent, from the limbus of the cornea and the ciliary region, thus lessening the danger of disastrous ciliary irritation and inflammation—the danger which Graefe soon discovered and shunned. The knife he used resembled more nearly that sold as Liebreich's than the one employed by Graefe. It was a very narrow, straight bistoury, which, by its narrowness and thinness, could be easily propelled through the corneal tissue, encountering the minimum of resistance, and being most easily directed in the manœuvre necessary to make a sufficiently large and clean corneal wound. To hold the eyelids open he used Graefe's silver-wire speculum. He usually gave the patient ether to profound anaesthesia, taking all precautions to lessen the danger of vomiting. To steady the eyeball he used the ordinary fixation forceps, applying them as closely as possible to the margin of the cornea exactly opposite the place where he intended to make the corneal wound.

THE CORNEAL INCISION.

Considerable art was required to make the cut just where it should be. He usually divided the cornea into four zones by drawing five imaginary lines. One passed through the centre of the pupillary space, with two above and two below. The upper and the lower lines just grazed the clear corneal edge, while the others were exactly intermediate. He commenced his incision usually about a millimetre from the clear edge of the cornea, upon the intermediate line. The instant the point of the knife entered the anterior chamber he directed it downward and forward until it reached the centre of the field of the pupil, going on in the plane of the iris, but avoiding its tissue. He then passed the knife onward, giving to its point a curved direction upward, and made the counter-puncture on the intermediate line at a point as nearly as possible opposite the wound of entrance or puncture. That manœuvre made the dimensions of the wound in the anterior chamber as large as the outer edge of the cut would seem to indicate, and the ends of it sharp and clean, and less likely to ensnare the

cut edges of the iridectomy. As the knife, in making the counter-puncture, emerged beneath the conjunctiva of the limbus, it was well to give it a somewhat quick thrust in order that the aqueous humor might not follow into the subconjunctival space and burrow there before the conjunctiva was pierced. In completing the corneal wound he endeavored to have three-fifths of its extent distinctly in clear cornea, approaching the opaque edge and yet its central portion, one-half a millimetre at least, from it. He thought that a wound made throughout in the opaque cornea or the limbus did not heal so well; moreover, he had seen ugly and even disastrous trouble set up in the ciliary region by carrying the entire wound in the limbus. He was very imperative on the necessity of having the wound large enough for the easy delivery of the lens. An insufficient wound was the worst possible defect in a cataract operation.

THE IRIDECTOMY.

In the iridectomy the iris should be coaxed out of the anterior chamber by a little gentle pressure with the horn-spoon over the upper ciliary region. It was better that the iris should prolapse than that the iridectomy should be introduced into the anterior chamber. If, however, the desired prolapse of the iris could not be produced in that manner, the forceps could be introduced. Usually the amount required was removed by three snips of the scissors. The aim should be to leave a clean-cut coloboma without jagged edges or any tags of iris in the corneal wound.

LACERATION OF THE LENS-CAPSULE.

The next step in the operation was the laceration of the lens-capsule. It had been proposed to deliver the lens capsule and all without laceration, but he had not been so favorably impressed by what he had read and seen as to be induced to try that method. The best that could be said for it was that it did not necessarily always cost a loss of the eye.

With reference to division of the capsule, he thought the practice had commonly been to use the cystotome freely and to break up as much of the anterior capsule as possible without coming in contact with the uveal surface of the iris too freely. He had never been able to convince himself that any considerable portion of the anterior capsule could be invariably cut out by any method of concurring incisions. He had, therefore, always contented himself with such a free division of that portion of the anterior capsule as extended from below the axis of the lens upward to its periphery, and sideways to the edges of the cut iris. Lately, acting upon a suggestion made by Dr. Knapp, he had confined his work with the cystotome more to the mere peripheral portion of the capsule, opening the sac of the lens along its upper and anterior edge, taking care not to lacerate the suspensory ligament or to open the vitreous chamber. That operative procedure was first suggested and done by Dr. Gruening in Morgagnian cataract, and Dr. Agnew thought the method was a most substantial addition to the extraction manoeuvres. It might be true that a secondary operation might be very frequently necessary to break a hole in the capsule which would become more or less opaque, but such a procedure was extremely common after the older method of free division of the capsule at the time of the operation.

PRELIMINARY IRIDECTOMY.

For a year or two he had resorted quite frequently to a preliminary iridectomy, hoping by so doing to lessen

the number of total losses after extraction. His experience had led him to believe that it was of value in exceptional cases only, or when we had more than usual reason to dread accidents at the time of the extraction operation, or certain bad after-complications.

At present he was in favor of the preliminary iridectomy: 1. In cases of known or gravely suspected fluidity of vitreous humor; 2. In cases of extreme marasmus, when the nutrition of the eye was very doubtful; 3. In cases in which an anæsthetic could not be used, and in which the patient had no self-control, or when from extreme deafness the surgeon was unable to command quick obedience on the part of the patient; 4. In cases of extensive pterygium or chronic conjunctivitis; 5. In some cases of synechia, anterior or posterior; 6. In cases of partial staphyloma.

MINUTE DETAILS OF THE EXTRACTION OPERATION.

Dr. Agnew then referred to certain minute details which he regarded as of the utmost importance, such as thorough removal of lens-crumbs by manipulating the cornea with partially closed eyelids; moistening the surface of the cornea if there was the slightest suspicion that its epithelial covering was growing dry; aiding the delivery of the lens by a little pressure on the eyeball, over the upper scleral lip of the corneal wound; bringing forward the lens by well-directed pressure with the horn-spoon, so that the nucleus and critical portion could be delivered together. Those difficulties would be at their minimum if the corneal wound was large enough.

THE USE OF ATROPIA AND ESERINE.

At one time Dr. Agnew thought it best to dilate the pupil with atropia before extracting the lens, but had discontinued the plan. He had not seen any reason for instilling eserine before the extraction, but on the contrary some cogent ones against its use at that stage—among others, that it now and then induced much irritation of the eye and active hyperæmia.

THE AFTER-TREATMENT.

Dr. Agnew then gave a somewhat detailed account of the after-treatment of the patient, such as related to covering the eye, and the general hygienic and medicinal management of the case. So long as the tarsal edges of the eyelids remained natural in appearance, not being in the slightest degree reddened or swollen, the scleral conjunctiva only moderately injected, the cornea clear, and the anterior chamber neither muddy on the one hand, nor too clear and too deep on the other, and the iris changed but little from the color of that in the fellow-eye, and the reflex from the pupillary field was either clear and black or only a little milk-and-water looking from the presence of a few thin crumbs of cortical lens matter, we might remain at ease. Usually, little after-treatment was required of a surgical kind, however, and we simply had to meet inflammation in some one of its acute or subacute forms. He felt, however, that after having done a good clean extraction through a sufficiently large corneal wound, we might, as a rule, content ourselves by vigilant inactivity.

METHOD OF APPLYING COLD TO THE EYES.

His method of applying cold to the eyes was by means of pieces of muslin that had laid for some time upon a block of ice.

When atropia caused irritation, duboisia should be substituted for it.

STATEMENT OF RESULTS IN THE GROUP OF 132 CASES.

By Graefe's method there were 80 successes, 11 partial successes, and 8 failures.

By Graefe's method, with preliminary iridectomy, there were 22 successes, 2 partial successes.

By Liebreich's method there were 6 successes and 2 failures.

By Le Brun's method there was 1 failure.

The successes were, 81 $\frac{3}{4}$ per cent.; partial successes, 9 $\frac{1}{8}$ per cent.; and the failures, 8 $\frac{1}{4}$ per cent.

STATEMENT OF RESULTS OF THE WHOLE 250 CASES.

By Graefe's method there were 146 successes, 20 partial successes, 15 failures, and 3 unknown.

By Liebreich's method there were 21 successes, 2 partial successes, and 6 failures.

By Graefe's method, with preliminary iridectomy, there were 22 successes and 2 partial successes.

By Le Brun's method there were 4 successes, 2 partial successes, and 1 failure.

By the flap operation there were 6 successes.

The successes were 79 $\frac{3}{8}$ per cent.; partial successes, 10 $\frac{3}{8}$ per cent.; failures, 8 $\frac{1}{8}$ per cent.; and unknown, 1 $\frac{1}{8}$ per cent.

Further analysis was read, after which Dr. Agnew gave a detailed report of two cases of unusual interest, and which illustrated the value of certain steps in the operation. Special reference was made to beneficial results following the administration of large doses of calomel [fifteen to twenty grains], when there was reason to believe that the vicinage of the blood-vessels was occupied by lymph-cells.

The paper being before the Academy for discussion,

Dr. H. KNAPP remarked that on nearly every point he agreed with the author of the paper. The corneal section was the same he had practised for a long time. He thought Dr. Agnew was a little too severe in his criticism on the operation of

REMOVAL OF THE LENS IN ITS CAPSULE.

Besides some disadvantages, the operation had one remarkable advantage—and that was, that it did not produce iritis. There might be loss of vitreous, opacities in the vitreous, and perhaps also the results might not be so lasting; but there were quite a number of perfect results obtained from that method in hands which were practised in its performance.

INFLAMMATORY REACTIONS.

With regard to inflammatory reactions following cataract extraction, he fully agreed with Dr. Agnew, that the greatest liability to them came from *too small* a corneal section. When that section was sufficiently large, almost all the other steps in the operation were easy. The section of the iris should be thorough, and care should be taken that it did not become wedged into the edges of the wound. So long as the sphincter edges were not cleanly in the anterior chamber there was danger.

EXCISION OF A QUADRANGULAR PIECE OF THE LENS-CAPSULE.

Dr. KNAPP referred to the various methods of opening the lens capsule with the view to avoid inflammatory reaction, and remarked that for about ten years he had practised excision of a quadrangular portion of the capsule, but even then reaction processes had been distinct. He thought it best to open the capsule as little as possible. He then gave the results obtained in 461 cases of cataract extraction

which he had performed in Heidelberg, and in 360 cases in which he had performed the operation in the city of New York. Among the 461 cases there were 33 failures, and among the 360 cases there were 36 failures. The capsule was opened at the periphery in 67 cases, and of these there were 4 failures. Of the whole the failures amounted to only eight and nine per cent.

Dr. ROOSA remarked that while the statement was perhaps entirely correct, in one aspect, that there had been a steady increase in success since the introduction of von Graefe's modified operation, he doubted if the statistics of large eye infirmaries, where there were a number of operators, had shown that any extraction operation had been made so easy that the results were much better than those obtained from the old flap operation, and without iridectomy. He had always thought, notwithstanding his profound regard for von Graefe, that too much credit had been given to him for this operation. He thought Graefe's operation as simply and practically a change of the old inconvenient knife to one which was convenient, with a little different manner of making the incision. He believed that the millennium of cataract extraction would not be seen until the day arrived when the lens could be removed entirely with its capsule. Until that could be performed successfully, and performed without iridectomy, the highest degree of success would not be obtained. Just how that was to be done he was hardly able to suggest. The operation of iridectomy marred the beauty of the eye, and it was with pride that he referred to the cases in which Dr. Agnew, years ago, operated by the old method, and the patients came from the operation with a circular pupil and vision undisturbed.

PERIPHERAL SECTION OF THE LENS-CAPSULE.

Dr. GRUENING remarked that he was the first to introduce the peripheral section of the capsule of the lens. It was never performed or suggested by von Graefe, even at the time when scooping out the lens was recommended. Dr. Gruening then gave an account of the step which led him to the adoption of that modification, particularly for the extraction of a Morgagnian cataract.

Dr. THOMAS R. POOLEY thought it desirable that a better word than that now employed for peripheral laceration of the capsule should be found. With reference to the cases in which Dr. Knapp had made the operation by this new method, he had assisted in the performance of very many of them, and had been surprised at the very few in which there was subsequent reaction of any kind whatsoever. In the cases in which the quadrangular laceration was made, certain forms of reaction occurred quite frequently, but there was a striking absence of iritis. With reference to the preliminary iridectomy, he directed Dr. Agnew's attention to a remark he had formerly made to him, that one of its advantages was, that about the region of the cicatrix was set up a hyperemia which was favorable to the healing of the cataract section that was to follow.

Dr. HOLCOMBE agreed with Dr. Roosa regarding removal of the lens without removing a portion of the iris, and asked Dr. Agnew with reference to the proportion of his cases in which vomiting followed extraction of the lens, and its explanation.

PREPARATORY TREATMENT.

Dr. D. WEBSTER remarked that he had assisted Dr. Agnew in most of the last series of extractions, and their experience had shown that, as a general rule, it

was better not to delay an operation for the purpose of placing the patient upon a course of preparatory treatment.

Drs. Hutchinson of Utica, and Matthewson of Brooklyn, were invited to participate in the discussion, but, owing to the lateness of the hour, declined to make any remarks.

DR. AGNEW, in closing the discussion, remarked that all agreed with regard to the apparent mutilation of the eye by the removal of a portion of the iris, but he believed that reliable statistics showed better results than were obtained by the old flap operation. He thought the statistics made before Graefe's time were not so reliable as those which had since been accumulated. The percentage of total loss was from three to four per cent. less since von Graefe suggested his improved method than formerly.

With regard to Dr. Pooley's question, he had not lost his confidence in the procedure.

The Academy then adjourned.

SURGICAL SECTION.

Stated Meeting, April 8, 1879.

DR. STEPHEN SMITH, CHAIRMAN.

PARALYSIS FOLLOWING FRACTURE OF CORACOID PROCESS OF SCAPULA.

DR. JAMES L. LITTLE reported a case of fracture of the coracoid process of the scapula from very slight injury, which was followed by complete paralysis of that side of the body.

TRAUMATIC RUPTURE OF ULNAR NERVE—PROPOSED OPERATION.

DR. L. WEBER reported a case of rupture of the ulnar nerve. He had proposed to operate by cutting down and tying the ends of the nerve together.

DR. A. C. POST regarded the proposed operation as a feasible one, and one which he should not hesitate to perform.

DYSENTERY—STRICTURE OF INTESTINE—LUMBOLOTOMY.

DR. POST reported a case of ulceration and stricture of the rectum resulting from severe dysentery, in which he had performed the operation of lumbolotomy with favorable results.

ABSCESS TREATED BY HYPERDISTENTION.

DR. POST also reported several cases of abscess which had been treated by Callender's method, or by hyperdistention, with good results. In one case the patient passed into a condition which Dr. Post regarded as due to carbolic-acid poisoning. An account of the case has appeared elsewhere [see RECORD, April 19, 1879, p. 378].

NEW INSTRUMENTS.

MR. STOHLMANN exhibited a large number of new instruments, and among them was

AN IMPROVED SUSPENSION APPARATUS,

devised by Dr. W. C. W. Glazier, which is illustrated in the adjoining woodcut, and bears the following description:

It consists, like Dr. Sayre's apparatus, of a cross-bar, a head-piece, a sling for each arm. The latter, attached by a buckle (L), are connected with the head-piece by a cord which passes over a pulley (K) in each end of the cross-bar, so that the weight is equalized. One end of this cord is attached to a pulley (H),

through which passes a second cord (G) that is attached by hooks to the head-piece, so as to allow a backward and forward motion of the head, thus equalizing the pressure between the chin and occiput, or en-

abling the patient to rest the whole weight coming on the head-piece, on the chin, or the occiput at pleasure.

The head-piece consists of two padded straps (A B C, D E F, lower figure), of unequal length, fastened together at A D by a thin piece of metal bent at right angles, very like the ordinary four-tailed bandage used in fracture of the lower jaw. It is applied in a like manner, with the exception that the ends, instead of being tied, are attached to the hooks on the cord (G), which passes through the pulley (H), the longer one crossing behind the occiput, after passing outside of the shorter one, over the angle of the jaw and mastoid process.

The suspension apparatus is applied in the following manner:

Holding the apparatus before you, attach the short strap (E D F) of the head-piece to the hooks on the end of the short cord farthest from you. Stand behind the patient, slip the arms into the arm-slings (M M), and attach the cross-bar to the elevating apparatus by the hook; pass the head-piece in front of the patient's face, resting his chin on the short strap at D. The middle of the long strap (A) is now in front of the chin, the two ends of which (C B) are brought behind the occiput, crossed, and attached to the hooks at the other end of the short cord.

Small patients, in struggling from fright, are very apt to allow the arm-slings to slip to the bend of the elbow. This does no harm, as they invariably flex the forearm, thus holding on in spite of themselves. It is possible that this may be the best position for the arm-slings, as the pressure in the axillæ is often very disagreeable. The cross-bar of this apparatus is 0.50 m. between the bearings of the pulleys, and is the right length for a child; for an adult it should be from 0.75 m. to 0.80 m. in length. The advantage of length is that the strap (E D F) thus becomes more nearly horizontal, thus preventing pressure on the sides of the face, by holding away the strap (B A C), which would otherwise press too heavily on the jaw.

METROPOLITAN THROAT HOSPITAL.—This institution has removed to 314 East Forty-fifth Street. The building, which is large and commodious (the gift of a well-known citizen), has been altered and thoroughly adapted to its present purposes.

CHICAGO MEDICAL SOCIETY.

Regular Meeting, April 21, 1879.

(Reported for THE RECORD.)

THE TREATMENT OF HEMORRHOIDS BY INJECTION.

PROF. EDMUND ANDREWS, President of the Society, read a paper on this subject.

He had corresponded with a large number of itinerant doctors—many of them the veriest quacks—who had practised this method of treating hemorrhoids, with many scientific surgeons who had used the method, and had asked through notices in medical journals for information on the subject, in response to which he had received many letters, some of them containing valuable information. By these means he had gathered statistics of over 3,000 cases treated by injection. He had no doubt that within nine years 10,000 cases had been so treated in this country.

The process seemed to have been the invention of a travelling charlatan of Illinois, in 1871. Afterward a large number of itinerants appeared; some of them had been regular physicians, who left their homes and practice, with the hope of making their fortunes by this new discovery; but most of them were quite ignorant of the science of medicine. The secret was sold to any who would buy, sometimes for large sums.

The substances generally used had been carbolic acid and olive-oil. Later, glycerine had taken the place of olive-oil. Some used the pure acid; others one part of the acid to 20 or 30 parts of the excipient. Ergot had been added by a few. Two used creasote, and two persulphate of iron.

The amount of fluid injected at one time had varied from 3 to 30 drops.

He had accounts of 3,295 cases treated by injection. Nine were said to have died from the effects of the treatment, but five of these were so imperfectly reported that he was not certain they could justly be charged to it; the other four were authentic. Five cases of dangerous hemorrhage occurred, 5 of hemorrhage less dangerous; 10 cases of abscess; 23 cases of sloughing (generally of not much more than the pile itself); 8 cases of suspected embolism of the liver; 1 case of abscess of the liver; 2 of severe inflammation; 2 of stricture of the rectum occurred; while 77 patients had violent pains lasting sometimes for several days; 6 were dangerously sick in bed from two to six months, and one had permanent impotence. One injection caused severe carbolic-acid poisoning.

Of the nine deaths, one was from a large abscess, fever and pyæmia—death occurring on the fifth day (the patient having previously been healthy); another was from apparent embolism of the liver—the liver was torpid, constipation existed, jaundice occurred, glands in the groins and axilla enlarged, and death from assthenia ensued nearly three months after the operation.

One patient was 84 years old, and the injection appears to have been made into the prostate gland. Death resulted in three days. Another case in a younger patient had a similar history and death.

The plan had been pursued by some of tearing open the hemorrhoidal veins with needles. In one case so treated severe suffering came on, and the family adviser being sent for, he found the opening made by the needles stopped with a small cork, which, being removed, the pain ceased.

The operation by injection was not painless in more than about one-quarter of the cases.

Of 3,000 cases, one in sixteen was known to have suffered some disaster, varying in severity from severe pain to death.

Large injections were more likely to produce embolism, abscess, and sloughing, but there was no proof of embolism of any other organ than the liver having occurred.

Strong injections of concentrated substances were liable to the same dangers, except as to embolism.

Pain depended on the locality of the injection; most pain was produced when the medicine was introduced near the verge of the anus. He had found the fear of embolism to be the chief objection practitioners had to trying the operation.

He thought the operation a proper one for certain cases. His conclusions were as follows:

1. The material to use is carbolic acid in oil or glycerine—1 part to 10, 20, or 30. If glycerine is used, morphine, chloral, or iodoform may be added as an anodyne. The dose for each injection should be 2 to 4 drops, and the interval between repetitions 4 to 10 days.

2. The surface of the pile should be protected by an application of some oil, as vaseline, before the injection is made, so that any leakage of the material may not cauterize the surface. The injection should be made very slowly; a very sharp needle should be used. The latter should not be withdrawn for some minutes after the fluid is forced in, lest leakage should take place.

3. Use this treatment for internal piles only, and inject only one pile at a time. Keep the patient in bed eight to ten hours after the operation, to avoid hemorrhage.

4. The rectum may be firmly tamponed above the hemorrhoids before the injection, to prevent the possibility of hepatic embolism, the tampon being allowed to remain twenty-four hours; but this measure is hardly necessary when small and weak injections are cautiously introduced.

Finally, he said the operation was not as safe or eligible as that by the ligature, but with caution was as good as any other method except the latter.

Correspondence.

A REPLY TO "NONNE."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In your issue of May 3d there appears a communication signed by "Nonne," who, by insinuation, makes grave charges against me. For those who know my views and actions upon the principles involved in the letter, it will appear in a proper light; but for those numerous members of the profession who read the RECORD, and who are not personally acquainted with me, I must pronounce those implied charges absolutely false and slanderous.

In conclusion, I call upon "Nonne" to abandon the protection of his alias, and to publish his name.

Yours truly, E. C. SEGIN.

NEW YORK, May 6, 1879.

REPORT OF FOUR BAD CASES OF
PYOTHORAX

CURED BY FREE INCISION AND THE USE OF DRAINAGE-TUBES.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—During the last year there has occurred in the practice of my father, Dr. John Burke, and myself, some cases of pyothorax, of which the four last were successfully treated by the above method. The cases are as follows:

CASE I.—Mary Q., æt. 18. After being in the coun-

try but a short time was taken with scarlet fever. In this disease she was attended by Dr. Burke; I seeing her but once. During her convalescence from scarlet fever she again fell sick, this time with pleurisy of the left side. In spite of all efforts, the fluid that distended her left pleural sac would not be absorbed. She was aspirated. It filled again. Aspiration was again resorted to, and this time the fluid contained pus. Patient's condition very low. Pulse 130. Respiration a short time after second aspiration unusually rapid. Temperature $103\frac{1}{2}^{\circ}$ F. I now saw the case with my father. A free incision was contemplated, but we aspirated again. This time a thin pus was contained in the pleural cavity. This relieved her for a few days. We felt she was rapidly sinking. We resolved to make a very large incision. It was accordingly done. A quantity of sloughy tissue came away. A drainage tube was inserted, and the cavity washed out with a solution of carbolic acid. Patient's temperature fell from 104° F. to 100° F. Appetite better. Pulse from 120 to 130 fell to 100 to 105.

For about two months the girl's condition improved. The cavity was washed out, in the beginning, twice daily with a fountain-syringe, and as the quantity of pus diminished, once daily sufficed for washing. During this period I injected the cavity with tr. iodinii, liq. iod. co. and strong solution of carbolic acid, but in vain; I never could sensibly diminish the amount of purulent discharge. Finally, without my efforts, discharge ceased for a week. I withdrew my tube. But unfortunately the cavity filled again. Again was it opened, and finally after two more months our patient was sent home to Ireland with the tube in place. Here she improved rapidly; discharge ceased, and the tube was withdrawn. Eight months after, patient was in good health and working on a farm.

CASE II.—I. M., et. 32, who was a hard drinker, contracted pleurisy of right side. The usual treatment employed. After a time, fluid failing to be absorbed, in spite of tonics, diuretics, and blistering, it was withdrawn with an aspirator. This was repeated three times, when Dr. Burke perceiving the patient's condition to be desperate, made a free incision and inserted drainage-tube. Temperature fell immediately, and appetite slowly returned. The cure was effected after the usual manner in four months. The only remarkable thing in connection with this case was the slipping of the drainage-tube into the cavity of the pleura, where it remained for three weeks, when one morning, after a prolonged fit of coughing, it was expelled, with a larger tube which had been inserted in its place.

CASE III. was that of a child two years of age. Pleurisy of left side. It was aspirated three times, when, pus occurring in the fluid, a free incision was made. The little patient, who before was almost in articulo mortis, became much better. A cure was effected after six months.

CASE IV. was also a child, aged eight years, whose condition became suddenly alarming, due probably to a change in contents of pleural cavity. Temperature before operation was 105° F.; pulse 165. Respirations extremely rapid. The aspirating needle was inserted on the left side, below the lower angle of scapula, but, as a thin pus exuded around the needle, it was decided by my father and myself to make a free incision. About a quart of pus and sloughy tissue was discharged. The minutiae of this case are unimportant. The child rapidly recovered, and is now going about, two months from operation, with tube in place. A little oakum bandaged over the mouth of tube preserves his clothes from being soiled. In con-

clusion, I must say that I believe many patients are lost through hesitancy in opening into pleura when the indications point to a purulent fluid. The operation, even in desperate cases, is not very hazardous to life; though I may state that, called in consultation to do this operation some time ago upon a child, it perished some short time after from shock. I must excuse myself in this case, as I feel convinced that an earlier resort to the free incision would have saved the child's life. Under the circumstances, however, I would again resort to the operation. I think that, previous to Mr. Lister's improvement in surgical dressings, most surgeons would have hesitated about putting a large drainage-tube into the pleural cavity. I think in some extreme cases the old plan was to introduce either a plug of oakum or sheet lint. The consequence was, that the pus did not escape freely, and the success of the operation was not as it is now. If I could, in these cases, have conveniently employed Lister's method, I think I might have shortened the period of convalescence.

MARTIN BURKE, M.D.

147 LEXINGTON AVE.

VENTILATION OF HOSPITALS.

TO THE EDITOR OF THE MEDICAL RECORD,

DEAR SIR:—I was recently called professionally to attend the veteran ventilating engineer, Prof. J. Wilkinson, of Baltimore, Md., who has spent the past three years in the Northwest in supplying, for a variety of purposes, the system known as sub-earth ventilation, which has of late been introduced in Prussia and other countries of Europe. The system has been in use in this and adjoining States more than two years, and is said to have proved *par excellence*. I have frequently heard of the remarkable results attained by its use, but had not familiarized myself with the detail of construction necessary, or the scientific principles involved in the system, until I formed the acquaintance of Prof. W., the inventor of it.

It has been mainly used, hitherto, in structures for the manufacture of dairy products, for which it has proved to be admirably adapted.

Confidently believing, as I do, that the system is superior to any other for hospital buildings, I wish to present it to the attention of the medical profession, for which I desire to avail myself of the columns of the RECORD, believing that to be the most useful and efficient medium of laying it before the largest number of the most intelligent medical practitioners.

I will describe the appliances used, and the results attained, which latter, I think it will be conceded, are just what constitute essential characteristics of all structures for human occupancy, and more especially of those that are to be the houses of the sick and demented.

Buildings are supplied with air by means of a subterranean air-duct placed in a stratum of earth in which the temperature is uniform perpetually. Both entrances of the duct are open: one to receive atmospheric air from the most salubrious point available, through a well or shaft with the bottom of which the duct connects; the other to discharge and distribute said air to all the apartments to be tempered and ventilated.

The supply of air is regulated by adjustable valves, and any required volume of it may be supplied to a building at the same temperature as that of the earth in which the duct is placed.

This uniform temperature in the air supplied is unaffected by the extremes of temperature in the external air, and is perpetually about 50° F.

The walls of the duct being of a lower temperature than that of the outer air in warm weather, when air is liable to contain an excess of humidity, it is condensed on the walls, and is absorbed by the clay bottom with which the ducts are constructed, and the air is delivered to the building in an anhydrous condition.

In case it is desirable to retain any of the humidity with which air is charged, this is secured by the use of a plurality of ingress shafts properly distributed along the line of the supply-duct, by the adjustment of valves in which air properly tempered and with variable degrees of humidity may be obtained. Additional devices for deodorizing and disinfecting to a still greater degree than that secured by the clay surfaced bottom of the duct have recently been invented and tested by Prof. W., and found to possess superlative potency, and their hygienic value is believed to be so great that an application for a patent for them will soon be made.

The walls of the duct being moistened by the condensation of vapor on them, they effectually arrest all dust, pollen, and motes floating in air, transmitted by the duct as it is now used. The duct has invariably proved to possess the power of removing ozone from the air.

Dairy scientists contend that ozone annually occasions a loss to the dairymen of the United States and Canada of hundreds of thousands of dollars. The effect of it on milk set for butter-making is, I am reliably informed, so disastrous that it has the effect, every summer, and several times during the same season, to reduce the amount of cream obtained from a given quantity of milk from 35 to 60 per cent. I believe that a substance in air, capable of precipitating acidification and the action of ferments to such a degree as does ozone, must materially augment the insalubrity of said air, and that means for its removal from air will add an invaluable factor in methods for securing the greatest degree of salubrity in the atmosphere of human habitations.

This system of ventilation is in use in central Mississippi, and is said to be very satisfactory.

It has occurred to me that it might prove well adapted to ventilating quarantine and yellow fever hospitals, for which I hope it will be tested ere that unwelcome visitor again appears in its favorite localities.

C. M. JOHNSON, M.D.

HARVARD, ILL.

SEDATIVE ACTION OF CALOMEL.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—The Committee of Antipyretics of the Therapeutic Society having under inquiry the sedative action of calomel, the following six cases have been submitted as illustrative of such action. Contributions of a like character from other members of the society will make all that relates to the question interesting, and tend to draw upon the private case-books of the profession at large for facts that belong to either side, affirmative or negative.

The sedative action of calomel is not so much a debatable point as the claim that is made that calomel, in certain doses, is potent as a cardiac sedative, *without being at all a depressant*. Tartar emetic is powerfully and promptly sedative, but it is, at the same time, dangerously, or, at least, distressingly depressing to the vital powers. If calomel is ever depressing, it is so when any drug having a sedative action would, in the nature of things then existing, be also depressing if exhibited instead of calomel.

The few cases here presented serve to show the actively sedative effect of calomel, wherein depression was not only a sequel of its action, but immunity from that condition was necessary for the safety of the patients.

These few cases, dating back to 1874, are selected because they are the very first, in my observation and practice, in which calomel had been called into requisition for other than its local action upon the liver and intestines, or its general alterative or supposed blood-depurating action if exhibited in minute doses long continued. I am conscious how unmethodically these cases were studied, which would not have been the fact had I realized at the time how novel, useful and bold was the method of treatment, and how much I should afterward prize my experience. To Dr. James R. Leaming is due my initiation into the practice which utilizes a previously unconsidered property of calomel, when given at certain times in certain doses.

I find the new lesson of value in a great variety of cases wherein the leading condition, in the early stage, is great vascular excitement, as shown by turbulent heart-action, excessive arterial tension, and bounding force of circulation, even before pyrexia is established.

To those who recall what I have published in the journals on scarlet fever, diphtheria, etc., it will be seen that mere observation through later years has not impaired my trust in the sedative action of calomel. The cases are as follows:

I. *Endopericarditis*.

II. and III. *Spasm* and threatened mania.

IV. *Irritative* (or nervous) fever.

V. and VI. *Gastric fever*.

CASE I.—The little daughter of Mr. M., of Forty-seventh street, about eight years old, was attacked in May, 1874, with acute inflammatory rheumatism, attended by violent cardiac symptoms. The case was in the practice of Dr. Leaming, but for convenience I was delegated by the doctor to attend, while he made occasional visits for observation and counsel.

During the 27th, 28th, and 29th of May the suffering was excessive whenever any suspension of the anodyne ("Dover's powder") was allowed. Notwithstanding the very liberal use of alkaline medicines and the opiates, the heart's action, on the 29th, increased to such a tumultuous state, the pulse became so bounding, and the temperature was rising so rapidly—to say nothing of the pain, which was only partially allayed—that an immediate consultation was called. Dr. Leaming requested me to write for grs. xv. of calomel, which, as soon as procured, was given, with a few grains of sugar, dry, upon the tongue. In less than one hour the whole aspect of the case changed.

Patient ceased to be fretful and restless. The heart, though revealing by the peculiar *bruit* its endocardial and pericardial inflammation, was, however, quieted almost to the normal state. The pulse was tranquil, the skin moist, and temperature cooling. Hours of refreshing sleep ensued, and after that the treatment which had been interrupted was resumed, with no further important hinderance during the progress of the case. The action upon the bowels was so slight that it was never known when a calomel stool had occurred, and there was no pyalism. This case was in some respects a revelation to me.

CASES II. and III.—In the autumn of 1874 a young man, *æt.* 20, had disgraced himself by some act of deception, and thereby forfeited his situation in business. The remorse and mortification were so great that he became melancholy and neglected himself.

After a few days he developed symptoms that threatened to be maniacal. This state terminated suddenly in convulsive spasms, which were repeated at various irregular intervals, as often as twenty or thirty times a day for three days before I was called to see the patient. I found great perturbation of the heart's action and a violence of arterial pulsation that indicated the need of a quick and efficient sedative.

I had in mind Case No. I. so promptly relieved under conditions of vascular energy not very dissimilar.

I administered at once hyd. chlorid. nitrate grs. xx., dry upon the tongue, and had the satisfaction of seeing an immediate suppression of all spasmodic symptoms, a quieted heart and pulse, a tranquillized mind, and a disposition to sleep. During the three days of violent recurring spasms I ascertained that it took two or three men to keep the patient in bed, and to restrain his frenzy sufficiently to prevent his doing himself an injury, and each fit would last from ten minutes to an hour.

CASE III. was nearly the counterpart of the one just described. It was a young woman taken with hystero-epileptiform convulsions, due to disappointment and constipation. She had fifty or sixty convulsions in twenty-four hours—some of brief duration, others nearly half an hour, and one or two an hour long. Between the paroxysms the mind wandered and insanely quarrelsome tendencies developed, everything giving offence, and anger was excited over imaginary opposition. Without any apparent tendency in the case toward cessation of the convulsive spasms, and while the cardiac and vascular excitement was raging up to the highest point of endurance, I was enabled, by one xv. grain dose of calomel, to instantly allay every morbid symptom and put the patient to sleep, which lasted, with comfort and refreshment, for five or six hours.

There was no impression upon the bowels that might not have been due to any mild cathartic, as only one medicinal stool occurred about eight hours after the dose was taken, and that without pain or sense of exhaustion.

CASE IV.—A boy, twelve years old, jumped out of a wagon without sufficient deliberation, as he was detected by the driver stealing a ride, and was frightened by some threat. He sprained his ankle so badly that he had to be carried to his home near by. The day after the accident I was called in. He had been allowed to go unattended by any physician since he was hurt until I saw him, and, consequently, was suffering great local inflammation and very high fever. I sought to reduce the temperature and the force of the circulation by cooling drinks, febrifuge medicines, and soothing local applications. I partially succeeded, but found in a few hours these symptoms returning, with a tendency to delirium. I gave a powder of calomel and dry sugar upon the tongue, not less than fifteen grains (as I had it with me, and measured it out myself), and in less than an hour the heart was beating with normal rhythm and force, the delirium was no longer threatened, skin moist and cool, and patient disposed to sleep. No unusual peristaltic action occurred from the calomel.

CASES V. AND VI.—These two cases were associated, occurring in sisters, aged respectively seven and nine years. They had made for their amusement some form of infusion that they called "tea," and, having consumed it, were very soon vomiting and retching with great violence and persistency. A neighboring physician gave lime-water and milk, and bismuth subnit., and finally succeeded in allaying

the vomiting; but both children were found by me on the following morning to be in a state of nervous irritability and towering fever. The hypogastrium was tender and painful upon pressure, with a tendency to a renewal of the vomiting whenever anything was given by the mouth. I thought of my sedative dose of calomel, and, having given each child xii. grains dry upon the tongue, soon had the pleasure to see the flush of febrile excitement pass off, the pulse fall to the normal frequency and fullness, the skin to react in the physiological direction, the stomach to lose its irritability, and the repose of sleep to ensue. No relaxation of the bowels occurred in either case.

These results, as a matter of course, were so unexpectedly good, and apparently so free from any harm, that they became suggestive of a wide range of possibilities in conditions that require prompt sedation without depression.

HYDRIODIC ACID.

A SUBSTITUTE FOR IODIDE OF POTASSIUM.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Seven years ago, while with my father, at that time practising in Chester, S. C., I found that he was using hydriodic acid in place of iodide of potassium. The case that suggested its use was one of asthma; for many years the patient had suffered from this troublesome affection. Whenever she contracted an ordinary cold it would extend to the chest and cause at once persistent asthma, which, if left to itself, would last for weeks. A full dose of morphia would relieve the spasmodic and labored respiration, and large doses of iodide of potassium would remove the bronchitis in a short time. Often the iodide would irritate the stomach and seriously interfere with digestion. To get the best effects it was necessary to give from fifteen to twenty-five grains of the iodide three times a day. Hydriodic acid was prepared by mixing one drachm of iodide of potassium with ninety grains of tartaric acid, and dissolving in four ounces of water. On trial it was found that one teaspoonful of this mixture had as much influence on the bronchial surfaces as twenty grains of iodide of potassium, and produced no bad effect whatever on the stomach. The only difficulty was, that the simple solution soon decomposed and set free the iodine; to obviate this it was mixed with a very heavy syrup, and when properly prepared it made a clear solution which could be kept several days without showing much sign of decomposition.

Gaseous hydriodic acid (HI) is rapidly and perfectly absorbed by water, but being held by a feeble chemical affinity the hydrogen soon becomes disengaged and sets free a corresponding amount of iodine, which, being soluble in hydriodic acid, passes into solution, colors it red, and renders it too irritating for internal use. As 100 parts of hydriodic acid consist of $99\frac{20}{107}$ parts of iodine and $\frac{7}{107}$ parts of hydrogen, it will be seen that it is nearly all iodine, and when not decomposed it is entirely non-irritant and pleasantly acid to the taste. To make the syrup it requires care, and most drug shops will get up sufficient decomposition in the mixing to render the solution useless. Several months ago I sent for R. W. Gardner, of 170 William Street, New York, whose syrups of the hypophosphates I had used with much satisfaction, and suggested that he would try and prepare a syrup of hydriodic acid. He succeeded in making a syrup containing forty minims of the dilute acid to the ounce,

representing $6\frac{1}{100}$ grains of iodine, which corresponds to $8\frac{1}{100}$ grains of potass. iod., which keeps perfectly. Two teaspoonfuls of the syrup is an average dose.

I have had some patients that could not take even very small doses of iodide of potassium, or iodine in any form, without producing severe iodism. Some of these cases gave distinct accounts of active poisoning, others seem to have the idiosyncrasy show itself with the first dose of iodine. Other patients easily bear 25 grs. potass. iod. three times a day, for weeks at a time. In the use of hydriodic acid I have seldom found it necessary to increase the usual dose to get the desired effect. It would seem that iodide of potassium becomes active by being converted into hydriodic acid.

For the past six years I have had uniformly good results in the use of hydriodic acid in bronchitis, and in chronic or subacute cartarrhal diseases. I have found that it acts as an irritant, and does more harm than good during acute febrile stages. I have also used it in chronic malarial poisoning, and in Graves's disease, and would recommend its use in place of iodine in goitre and adipose tumors. In a case of the latter it relieved the dull pain about the tumor and reduced the weight of the body slightly (the patient being very fleshy). I have not used hydriodic acid in syphilis long enough to give an opinion as to its value in this disease.

The text-books on therapeutics do not even mention hydriodic acid, and the *National Dispensatory*, edited by Alfred Stillé, M.D., and John M. Maisch, Ph.D., says: "Pharmaceutically, hydriodic acid is a very unsatisfactory preparation." "It possesses no medicinal value."
W. GILL WYLIE, M.D.

49 W. FORTIETH STREET, NEW YORK, March 26, 1879.

New Instruments.

THE METRO-CLYST, OR INTRA-UTERINE IRRIGATOR.

By JOHN S. COLEMAN, M.D.,

AUGUSTA, GA.

The interesting communication in THE MEDICAL RECORD for March 8, 1879, on "The Treatment of Hemorrhage in Abortion," by Dr. W. T. Lusk, recalls a device mentally evolved by me some months since.

The instrument consists of a wire frame and rubber tubing, and has recently been made for me by Messrs. John Reynders & Co., of New York. For its name, I am indebted to my erudite friend, Dr. A. Sibley Campbell.

Though this instrument was originally devised solely for the use of tinc. of iodine in the treatment of hemorrhage in abortion, I confidently present it to the profession as an invaluable aid in the treatment of many of the diseases of the cavity of the uterus; viz., chronic endometritis, suppurating fibroids or polypi, putrescent fetal remains, and in many instances where antiseptics is required. In cases of abortion, with subsequent foetid discharge, I have used with good results Battey's "iodized phenol" and Emmet's applicator.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from April 27 to May 3, 1879.

GIRARD, J. B., Capt. and Asst. Surgeon. Assigned to duty as Post Surgeon at Fort Davis, Tex., relieving Asst. Surgeon Woodruff. S. O. 83, Dept. of Texas, April 21, 1879.

HALL, J. D., Capt. and Asst. Surgeon. Assigned to duty at Fort Griffin, Tex., relieving Asst. Surgeon Powell. S. O. 83, C. S., Dept. of Texas.

WOODRUFF, E., Capt. and Asst. Surgeon. Assigned to duty as Post Surgeon at Fort Stockton, Texas, relieving Asst. Surgeon Hall. S. O. 83, C. S., Dept. of Texas.

BROWN, P. R., 1st Lieut. and Asst. Surgeon. Relieved from duty at Fort Shaw, and assigned to duty at Fort Bennett, Dak. T. S. O. 39, Dept. of Dakota, April 22, 1879.

MERRILL, J. C., 1st Lieut. and Asst. Surgeon. Assigned to duty at Fort Shaw, M. T., relieving Asst. Surg. P. R. Brown. S. O. 39, Dept. of Dakota, April 22, 1879.

POWELL, J. L., 1st Lieut. and Asst. Surgeon. When relieved, to report in person at these Headquarters for further orders. S. O. 83, C. S., Dept. of Texas.

MEDICAL SOCIETY OF NEW JERSEY.—The annual meeting of the Medical Society of New Jersey will be held in the Palisade House, Englewood Cliffs, on Tuesday evening, the 27th inst., and will continue in session the following day. Steamers will be in readiness at Pier 34, or Twenty-fourth Street, North River, New York, on Tuesday afternoon, to convey all physicians and their families who may wish to attend the meeting, free of charge. Steamer Idlewild will leave at 3.30 o'clock, and steamer Chryse-nah at 4 o'clock.

WM. PIERSON, Jr., Sec'y.

ORANGE, May 1, 1879.

RESOLUTIONS ON THE DEATH OF DR. HAYS.—At a meeting of the Philadelphia College of Physicians, held on April 15th, to take action with reference to the death of Dr. Isaac Hays, the following resolutions were unanimously adopted:

Resolved, That the Fellows of the College deeply regret the death of their late able and distinguished associate, Dr. Isaac Hays.

Resolved, That having in view the welfare of the college, he took throughout his fellowship a watchful and active part in its proceedings; and, while health

and vigor permitted, was unusually constant in his attendance at its meetings.

Resolved, That as a member of the Building and other committees, and by his general participation in its affairs, he rendered signal service to the college, contributing greatly to its prudent and conservative policy, and leaving upon all that he said or did the impress of his cautious and deliberative mind.

Resolved, That he has largely contributed by his long and able editorship of the *American Journal of the Medical Sciences*, and by his other valuable works, to the creation and diffusion of a sound and healthful medical literature, and thus made himself, in an enviable degree, an instructor and benefactor of his profession.

Resolved, That by his faithful services of twenty years in connection with Wills Hospital, and by his various publications on ophthalmic surgery, he gave a wholesome impulse and direction to that department, and won for himself a distinguished place among the oculists of the country.

Resolved, That the Fellows, appreciating his learning and his worth, and grateful for services cheerfully rendered during his long and pleasant association with them, will ever cherish a kind and affectionate regard for his memory.

In moving the adoption of the resolutions, Dr. Samuel D. Gross made some remarks eulogistic of Dr. Hays, speaking of the *American Journal of the Medical Sciences*, of which he had been for so many years the editor, as a monument of his industry and learning, no word in which was unworthy of the highest conception of the functions of the editorial chair. He said that regret for the great loss of Dr. Hays in his office was, however, not a little mitigated in that his mantle had fallen upon a worthy successor, his son, Dr. I. Minis Hays, who, full of energy and ability, promises to continue the *Journal* in its long career of success.

RICHARD A. CLEEMANN, M.D.,
Secretary of the College.

UTERINE AND VAGINAL APPLICATIONS—Dr. Sueserott, of Chambersburg, Pa., writes: "Long familiar with the almost magical effect of a thick cream of subnit. of bismuth, mixed in pure glycerine, when applied to blistered surfaces, burns, and ulcers externally, as well as the soothing and curative action of the salts of bismuth in ulceration of the stomach, I conceived the idea of using it in ulceration of the cervix uteri. A sufficient experience in that direction has convinced me that the result is no less wonderful than when externally applied. This may possibly be no new suggestion to some of your readers. But, acting on the principle of 'proving all things, and holding on to that which is good,' I would earnestly urge upon all gynecologists, who are not fully satisfied with what they are now using, to give it a trial and report through the columns of your excellent journal. I have used a thick glycerole of tannin, dry tannin, glycerole of aloe, and the various astringent, sedative, and escharotic substances that have, from time to time, been suggested; but there is no one thing that I have applied that gives as much immediate relief as the subnit. of bismuth and glycerine. The congestion of the cervix is at once abated by the glycerine through the exosmotic action that is set up, and the ulcers disappear as though waved away by a fairy's wand.

"If this article is not already too long you may append my method of making vaginal applications, which I will endeavor to illustrate. I have a glass

tube, a little longer than, and sufficiently small to pass into, an ordinary reflecting glass speculum. I take a pledget of absorbing cotton, on to which I have tightly looped a cord of sufficient length to project beyond the vulva, when the cotton is in contact with the womb. Having passed the cord through the tube, I draw the cotton in to the extent of an inch or two, so as to have sufficient space for whatever quantity of bismuth and glycerine, tannin, aloes, or whatever I am about to introduce within the vagina. The speculum having been properly applied, so as to bring the ulcerated surface within view. I next insert the tube, with its contents, within the speculum, and with a wire-probe, armed with a disk of metal about three-fourths the diameter of the tube, I press the cotton to its place, withdrawing the tube and holding the application *in situ* until the speculum is partially removed. As soon as the walls of the vagina fall over the cotton, the probe may be taken away and the medicament is just at the spot desired. My custom is to allow it to remain for thirty-six or forty-eight hours, when the cotton is easily removed by means of the cord by the patient herself. After removal I recommend an injection of a saturated solution of borax or slightly diluted whiskey, once or twice a day for two days, when I make another application. If the pledget of cotton is too large it will not remain in place as well as a smaller one; but this must be determined by the judgment of the operator. A glass rod would serve a very good purpose in pressing the cotton out of the tube, and where certain articles, such as tinct. of iodine, have been used, would be better than metal. Its liability to fracture in handling is the only objection that could be urged."

NORTHEASTERN DISPENSARY—REPORT FOR THE YEAR 1878.—This report shows an increased amount of work done by this dispensary. The number of cases treated during the year was 21,438, an increase of over a thousand upon last year. The dispensary treats, therefore, about one-twelfth of all the cases that apply for aid to these institutions. About 3,000 of the patients were treated at their homes, each receiving an average of three calls from the visiting physician. Only ninety-three vaccinations were made during the year, the remarkable freedom of the city from small-pox accounting probably for the few applicants for such relief. A new class for nervous diseases has been established, and this, with the increased number of patients, has caused a small deficit in the treasury.

MORTALITY OF SCARLATINA AMONG THE TENEMENT-HOUSE POPULATION.—Dr. D. W. Perham, one of the district physicians to the Northeastern Dispensary, gives some statistics in regard to scarlatina among the tenement population, which, considering the surroundings, show a surprisingly light mortality. In 104 cases treated during the past winter there were eight deaths. Of these two were from scarlatina maligna, three from acute nephritis, and one from asthma caused by a submaxillary abscess. The youngest patient treated was seven months old. Most cases were treated with M. ij. tr. digitalis every two hours, and M. iv. tr. ferri chlorid., with gr. iv. potas. chlorid. every two hours, the medicines being alternated. If this medication was followed up very vigorously, we feel it our duty to compliment the constitution of the average tenement-house child. There were given also, if the fever indicated it, sulphate of cinchonidia in five-grain doses, twice a day. No applications to the throat or skin, and no alcoholic stimulants were used. The statistics are much to the doctor's credit.

Original Lectures.

THE PERSONAL IDENTITY OF THE LIVING AND OF THE DEAD.

TWO LECTURES DELIVERED BEFORE THE CLASS IN THE AUXILIARY DEPARTMENT OF MEDICINE.

By JOHN J. REESE, M.D.,

PROFESSOR OF MEDICAL JURISPRUDENCE AND TOXICOLOGY IN THE UNIVERSITY OF PENNSYLVANIA.

(Reported for THE MEDICAL RECORD.)

LECTURE II.

THE IDENTIFICATION OF THE SKELETON CONTINUED:

1. ITS AGE; THE ORDER OF DEVELOPMENT OF THE FIRST SET OF TEETH—THE DEGREE OF OSSIFICATION AS A MEANS OF IDENTIFICATION—THE PRESENCE OR ABSENCE OF CERTAIN TEETH; 2. ITS SEX; 3. ITS STATURE, WITH A DISCUSSION OF THE SO-CALLED "RULES OF PROPORTION" AS LAID DOWN BY DR. GOULD AND BY M. DE ST. LUCIA—THE EXISTENCE OF FRACTURES, DEFORMITIES, AND CALLUS AS MEANS OF IDENTIFYING A SKELETON, ETC., ETC.

If the only part of the skeleton which is discovered is the *skull*, there can be no difficulty, usually, in recognizing it as human; the only possible doubt might arise about its belonging to one of the higher orders of apes. This mistake, however, could scarcely occur to one versed in comparative anatomy.

The question whether, from the examination of a skull simply, it is possible to decide to what *race* the individual belonged—Caucasian or otherwise—I do not think can be answered with certainty. Doubtless, well-marked *typical* skulls may be identified as belonging to some particular race, *e. g.*, the Negro or Caucasian; but we must remember that these points of distinction shade away, in many instances, so as to make it extremely difficult, if not impossible, to give a medico-legal opinion in an isolated case.

Another point to be noticed here is the importance of ascertaining whether all the bones submitted for inspection belong to one and the same skeleton. The mere fact of their being discovered together does not necessarily prove it, since they might have been so placed designedly for the purpose of eluding detection.

In the identification of the dead by means of the skeleton, or by detached bones, the three leading points to determine are the age, the sex, and the stature.

THE AGE AND THE ORDER OF DEVELOPMENT OF THE TEETH.

This can usually, in young subjects, be pretty accurately determined by the development of the teeth, and by the progress of ossification in the different bones. In the skeletons of newly-born children, and before the teeth have appeared, it may become important for the medical jurist to be able to decide upon the age, in order either to confirm or rebut a charge of infanticide. It is authoritatively stated that in the jaw of a child at full term there will always be found the rudiments of twenty-four teeth—twenty primary teeth and four permanent molars. Hence, if only the jaw of a child can be found, medical evidence may be given of its probable age. The average date of the eruption (or *cutting*) of the teeth, I would remind you,

is as follows: The four central incisors appear in from *five to eight* months; the four lateral incisors in from *seven to ten* months; the four anterior molars in from *twelve to sixteen* months; the four cuspidati in from *fourteen to twenty* months; and the four posterior molars in from *eighteen months to three years* (Bell). Between six and seven years the jaws contain forty-eight teeth—twenty temporary ones, in a perfect state, and twenty-eight permanent ones in an imperfect state of development, and placed behind the temporary teeth, which they are to replace. According to Mr. Saunders, the order in which the permanent teeth appear is as follows: At *seven* years the four anterior molars; at *eight* years the four central incisors; at *nine* years the four lateral incisors; at *ten* years the four anterior bicuspids; at *eleven* the four posterior bicuspids; at *twelve to twelve and a half* years the four cuspidi; and at *thirteen to fourteen* years the four second molars—making the whole number of teeth at this period to be *twenty-eight*. The four remaining teeth (*dentis sapientie*) do not usually appear until eighteen to twenty-one years of age. Generally, the teeth of the lower jaw are cut first. You must not forget, however, that some irregularities may occur in the appearance of the teeth: the above description is intended to apply only to the average cases. Now, let us take an example or two, by way of illustration. Suppose we were to discover the jaw of a child in which *twelve* permanent teeth were apparent—eight incisors and four molars; we should decide that the age was *nine years*. If the jaw contained *twenty-four* permanent teeth—eight incisors, four molars, eight bicuspids, and four cuspidi—we might conclude the age to be *thirteen years*; and so on. Before closing this branch of the subject I have one other observation to make. There are two diseases which affect the growth of the teeth, *viz.*, rickets and syphilis. In a rickety child the first teeth do not usually appear until after the twelfth month; whereas, in cases of congenital syphilis, the teeth appear before the sixth month, but have a very peculiar look. They are notched, and are apt to be brittle and to crumble easily.

THE DEGREE OF OSSIFICATION AS A MEANS OF ACCURATE IDENTIFICATION.

As already mentioned, the age of the skeleton is also indicated by the *degree of ossification*, especially in early life. According to Beelard, the extent of ossification in the lower epiphysis of the femur affords the most certain evidence of the age of the fetus and of the new-born child. Thus, if no ossific point can be seen in this cartilaginous epiphysis, it is certain that the fetus has not attained to the eighth month of utero-gestation. If the osseous deposit is as large as a poppy-seed, it is probably in the last month; and if it has acquired the diameter of a line and a quarter to one and a half, it has reached the full period. If the point of ossification measures three lines or more, it may be assumed that the child has lived after its birth.

The length of the skeleton of a new-born child is about sixteen inches (average). At the end of the *first* year, ossification has commenced in the extremities of most of the long bones; and this progressively advances from year to year, until the whole process is completed, and the epiphyses of all the long bones are united at full maturity, which in the male may be considered to be twenty-four years, and in the female twenty-two years. After this period, or when ossification is once completed, it is difficult to determine the age by an examination of the bones. It should be remem-

nered, however, that the different bones of the sternum do not unite until about the fortieth or forty-fifth year; and union between the sacrum and os coccygis is not usually completed until fifty-five to sixty years of age. In old age the bones become lighter in weight and more brittle, from the loss of their animal matter; they are also darker in color, and the flat bones become thinner from the absorption of their diploë. In the skull of the aged the sutures are more or less obliterated; and if the teeth have been lost, the alveolar processes become absorbed, and the appearance of the lower jaw undergoes a well-marked change, consisting in the widening of the angle at its neck, and a general rounding of the bone, which imparts the characteristic senile expression to the mouth of the aged. Now, the discovery of such a jawbone would positively determine the age to be about sixty years or over.

THE PRESENCE OR ABSENCE OF CERTAIN TEETH.

The presence or absence of certain *teeth* in the head has frequently been the means of determining the identity of the body. So also the presence of artificial teeth, with their mechanical appliances, has furnished the strongest corroborative evidence of such identification, as in the celebrated Parkman-Webster case, where the artificial teeth, discovered undestroyed in the fire in which the head had been burnt up, were positively identified by the dentist, who had manufactured and fitted them some years before. So, likewise, the remains of the Marchioness of Salisbury, discovered among the burnt ruins of Hatfield House, were identified by the jawbone having gold appendages for artificial teeth (Gay).

THE SEX OF THE SKELETON.

This can usually be determined from the skeleton, if entire, without much difficulty. I need not here go into a detailed description of the difference, well marked between the male and female skeleton; I refer you for these points to your instructions in anatomy and gynecology. Suffice it to say, that the corresponding bones of the skeleton differ in size, strength, weight, and prominences. There are certain recognized differences in the head and thorax; but it is in the *pelvis* that the most characteristic differences are observed. The male pelvis is narrower and deeper than the female. In the latter the *ossa ilii* are flatter and more everted, giving the whole pelvis a greater capacity; the sacrum is broader and turned more backwards; the arch of the pubis much wider; the greatest diameter is the bilateral, whereas in the male it is the antero-posterior. The foramen ovale in the female is triangular; it is more oval in the male; the acetabula are farther apart in the female. It is understood that these peculiarities in the female pelvis are not exhibited until after puberty. From a fragment of a bone merely, I should judge that it would be hazardous to undertake to determine the sex; and the medical jurist should certainly exercise much reserve in giving an opinion in such a case.

THE STATURE OF THE SKELETON.

When the whole skeleton has been preserved, and none of the ends of the long bones have been lost by decay, the original height may be pretty accurately calculated by adding an inch and a half to two inches, for the soft parts, to the length of the skeleton. But even here, absolute accuracy cannot be attained, chiefly on account of variations in the curve of the spinal column in different individuals. Dr. Dwight assumes, as the result of numerous observations, that the total

height of the intervertebral cartilages is 25.6 per cent. of the entire length of the spine.* As a collateral aid in estimating the stature, we may have regard to the generally accepted rule that the top of the symphysis of the pubes is about the centre of the body in average women; whilst in men, the centre is a little below the symphysis.

THE "RULES OF PROPORTION."

If only certain bones of the skeleton can be found, the estimate of the stature becomes much more difficult and uncertain. The so-called "rules of proportion" of the human body are not to be relied on here. In case of loss of the head, the rule laid down by Dr. Gould is "to find the height of the spine of the seventh cervical vertebra from the ground, and add to this 9.95 inches, which is the average height from this point to the top of the head."†

M. de St. Luca (*Cosmos*, Oct. 2, 1863, quoted by Dr. Taylor) states that an approximative estimate of the stature may be obtained by measuring the length of the first phalanx of the middle finger, thus: this phalanx is equal to one-fourth the length of the whole hand, including the carpus; the hand is one-fifth the length of the arm; double the length of the arm (or the two arms stretched out transversely), added to the length of the two clavicles, together with the breadth of the sternum, is equivalent to the height of the body. In applying this rule, however, we must not forget that the length of the hand, and especially that of the fingers, varies materially in persons of the same height; and so trifling a variation in the first phalanx of the middle finger as the one sixteenth of an inch, would, according to this method of calculation, figure up as great a difference in the total result as two and a half inches.

THE EXISTENCE OF FRACTURES, DEFORMITIES, AND CALLUS

in a skeleton, sometimes afford valuable aid in its identification, even many years after death. In relation to the production of *callus*, it is well understood that this substance is the product of the reparative inflammation of bones; and that its presence is a certain indication that some time must have elapsed between the injury and the death of the individual.

Some notable illustrations might be given of the identification of the skeleton by means of the above marks, and even of determining the actual cause of the violent death. In the year 1823, a soldier living in the south of France suddenly disappeared; and although there was a strong suspicion of his having been murdered, more than two years elapsed before the authorities interfered, and search was made for the missing man. Some human remains, chiefly bones, were discovered in the garden of the suspected murderer. Of course, it became necessary to identify this skeleton. It was remembered that the deceased had a singular personal deformity, in possessing a sixth finger on the right hand, and a sixth toe on the left foot. On examination it was ascertained that the fifth metacarpal bone of the right hand was shorter and broader than the corresponding bone of the other hand, and further, that there were two articulating surfaces on its digital end, indicating clearly the existence of a supernumerary finger. In the same way the fifth metatarsal bone of the left foot showed two distinct articulating faces on its digital extremity, in-

* The Identification of the Human Skeleton, by Thomas Dwight, M.D. Boston, 1878.

† *Ibid.*

dicating the existence of a supernumerary toe. Besides this, the age and stature of the skeleton corresponded with those of the missing man. But even further than this, a close inspection of the skull revealed the distinct marks of a depressed and radiated fracture of the temporal bone, which showed no sign of repairation by the formation of callus. Evidently then, death had occurred very soon after the fracture of the cranium, and, in all probability, as the direct result of violence.

An instructive case is mentioned by Dr. Taylor, of an Englishman who was tried in India for the murder of a native, who had been beaten by the former, with the alleged effect of breaking his rib and subsequently causing his death. A skeleton had been dug up three months after the decease, which was almost completely denuded of flesh, the bones clean and dry; *one rib fractured*, with a deposit of callus around the broken extremities. The identity of these bones with those of the missing man was attempted to be established, but unsuccessfully, in consequence of their dry and denuded state—a condition altogether incompatible with so short a period of time as *three months* since death. Moreover, the amount of callus thrown out made it evident that more than a week must have elapsed before death took place—and therefore supposing the bone to have belonged to the deceased, that this fracture must have been produced some eight or ten days before death.

Sometimes, on the exhumation of bones, the medico-legal question arises, how long have they been buried in the ground? It is impossible to answer this question with any precision, after all the soft parts have disappeared—which commonly requires about ten years. In a dry soil, the skeleton will resist decomposition for a considerable time; bones have been found in a perfect state thirty or forty years after burial. As decomposition in bones progresses, they become lighter in consequence of the loss of animal matter, and the color externally grows darker; the ends gradually become brittle and crumble away, and finally the shaft of the bone undergoes the same disintegration, the animal matter alone remaining unaltered. Denugie states that the bones of King Dagobert were found in a tolerable perfect state, enclosed in a coffin and sarcophagus, at St. Denis, after the lapse of twelve hundred years; and Dr. Taylor mentions that the skeleton of William Rufus was found in a stone coffin at Winchester, nearly perfect, after seven hundred and eighty years' burial. The bones of Abelard and Heloise were so well preserved, that after a lapse of five hundred years the female skeleton could be readily distinguished from the male.

If the bones have undergone *calcination*, as when a body has been burned with the intention of destroying the identity, especially in cases of infanticide, it may still be possible to determine whether the remains are human, or those of one of the inferior animals, unless the calcination has been so complete as to reduce the bone to powder. In the latter case, although a chemical analysis of the ash might detect the *phosphate of lime*, this would throw no light upon the subject of inquiry, since the ash of human and animal bone is identical.

In some remarkable cases the identification of a skeleton has consisted in the discovery of its burial place. Thus the body of Henry IV. of England was discovered in quite good condition in Canterbury Cathedral, some four hundred and fifty years after its burial.

So, too, only fifteen years ago, the tomb of Charles I. was opened and its contents examined. His body

was identified by its well-known resemblance to pictures and busts of the king, by the pointed beard and unusually high forehead, and by the fact of the severance of the head from the body.

LARYNGEAL PHTHISIS.

By F. H. BOSWORTH, M.D.,

LECTURER ON DISEASES OF THE THROAT AT THE BELLEVUE HOSPITAL MEDICAL COLLEGE.

(Read before the County Medical Society, Monday, March 24, 1879.)

PART I.

WRITERS on purely clinical medicine, such as Louis, Cruveilhier, Trousseau, and others, as a rule, uphold the doctrine of the non-tubercular character of laryngeal phthisis; while Virchow, Rokitsansky, Foerster, Rindfleisch, and the first authorities in pathological anatomy, teach that the disease is primarily due to a deposit of tubercle. The former of these views, as more perfectly harmonizing with the development, progress, and clinical history of the disease, and more clearly explaining the pathological changes observed during its course, is the one adopted by the writer; and the object of this paper is mainly to present certain considerations as bearing on this question from a clinical standpoint. The term ulcer is one which in late years has fallen into an extremely loose usage in connection with the mucous membrane of the fauces, both at the hands of physicians and the laity, and the great frequency with which we hear of ulcerated sore throats would lead one to suppose it to be among the commonest of diseases, whereas, excluding the simple erosions or excoriations of the superficial layer of the mucous membrane met with in acute catarrhal inflammations, and confining the term ulcer to what it is, a solution of continuity, with a progressive loss of tissue, molecular death of the parts, it is, in truth, of comparatively rare occurrence.

In the twelve months from March 20, 1878, to March 20, 1879, there have been recorded at the Bellevue Throat Clinic 1,827 new cases. Of these there were 39 cases of syphilitic ulceration of the pharynx or soft palate, 35 cases of laryngeal phthisis, 21 in the ulcerated stage and 14 in the earlier stages; 18 cases of syphilitic laryngitis, 11 ulcerative and 7 showing other conditions, such as stenosis, etc.; 4 cases of specific ulceration of the tonsils, and 5 cases of epithelioma of the tonsil, palate, etc., making, in all, 80 cases in 1,827, or about 44 in 1,000.

It may be asserted as an axiom that ulceration of the mucous membrane of the throat never occurs as a purely local affection, unless possibly as the result of traumatism, but that it is always the local manifestation or accompaniment of a general condition or constitutional disease. Excluding syphilis, epithelioma, scrofula, and lupus, as embracing all the other varieties of chronic ulceration, and, of course, the ulcerations which sometimes occur in the exanthems, including scorbutus, we have left a group of cases of laryngeal ulceration which pursue so nearly the same definite course, present so closely the same appearances, and manifest so uniformly the same subjective symptoms, that we class them as constituting one and the same disease under the head of laryngeal phthisis.

We may define laryngeal phthisis, or the so-called tubercular laryngitis, as a disease characterized by the development in the mucous membrane of the larynx, under the influence of some marked general non-specific dyscrasia, of an ulcerative process, chronic in character and slow in its destructive progress, which

commences in the superficial layer of the membrane, and, if not arrested, extends to the deeper tissues, attacking the perichondrium and cartilages, involving them in caries and necrosis.

In the large majority of cases it occurs in connection with chronic pulmonary disease; but we meet with it alike in tubercular and non-tubercular disease of the lungs.

As a rule, it occurs after the development of the lung trouble, but it may also occur before it is possible to detect by physical signs any evidence that the pulmonary tissues are diseased, but in these cases there is manifest always an impaired condition of the general health.

It may occur, also, from scrofula, malaria, syphilitic asthenia, anæmia, chlorosis, Bright's disease, or any of those general conditions which markedly impair the health and weaken the power of resisting disease.

The upper air-passages, exposed as they are to the first ingress of the inspired air, with its varying temperatures and conditions of dryness or humidity; exposed, also, to the deleterious influence of whatever of impurities it may contain, such as particles of dust and irritating vapors or gases, are exceedingly liable to become the seat of a catarrhal inflammation, which, having occurred once, leaves behind it an especial liability to its recurrence.

The larynx is also the seat of a constant functional activity in the various movements involved in the acts of phonation, respiration, and deglutition, the influence of which in aggravating an existing morbid condition we are often too apt to overlook. If, then, to an existing catarrhal inflammation, with the above-mentioned unfavorable incidents of locality, there is added a blood condition inviting disease to the most weakened part, be it the tuberculous diathesis, the syphilitic, the scrofulous, or any of the conditions lowering the vitality of the system and lessening its power of resisting disease, we can easily account for these chronic and destructive ulcerations in the larynx, which we call laryngeal phthisis, without entering into the perplexities, bewilderingments, and discouragements of the question of tuberculosis; indeed, it is not an extravagant statement to assert it as the conviction of a very large proportion of physicians, that the science of medicine would to-day be further advanced had the word tubercle never found its way into medical literature. Discarding, then, the doctrine that tubercle plays any part in the production of laryngeal phthisis, and regarding the disease as one in which we have a catarrhal inflammation developing into an ulcerative process under the influence of the constant irritation of ceaseless functional movement, added to an impaired condition of the general health, and we have an explanation of the cause of the disease which more fully harmonizes with its development, clinical history, and course, than any other. That the constant movement to which the larynx is subject plays an important part in the causation of laryngeal phthisis is still further shown by the fact that the earliest manifestation of the disease is seen in that portion of the organ which is subject to the most constant and restless motion, viz., the arytenoid cartilages and the interarytenoid commissure, the special movements taking place in these parts being such as would naturally tend to aggravate and irritate an inflammatory condition, the commissure being folded upon itself, and squeezed, as it were, between the cartilages with each act of phonation and respiration.

A large proportion of cases of the disease occur in connection with and subsequent to the development of

pulmonary disease. The true explanation of this is believed to be, that the pulmonary disease is the cause of the laryngeal disease, and not that the two are developed from one and the same cause. A majority of cases of lung trouble are attended by more or less catarrh of the mucus lining of the larynx. This condition is aggravated by the constant motion to which the parts are subject in phonation and respiration. The constant cough which attends the lung trouble cannot but be an additional source of irritation; and, besides this, the membrane is being constantly bathed by the discharges, often of a fetid and offensive character, which pass over it from below. If, now, the pulmonary disease be of such nature as to lead to serious impairment of the general health, we have all conditions most favorable for the development of the disease we are considering, for the writer strongly holds to the belief that impaired vitality is the most essential factor in its causation.

Primary laryngeal phthisis, if not arrested, invariably leads to the development of pulmonary disease. It is generally said of these cases that the pulmonary disease already exists, but is masked by the laryngeal disease, and cannot be detected by physical signs. It is easier to believe that the pain, constant hacking cough, loss of sleep, interference with proper nutrition by the painful deglutition, and the fetid discharges poisoning every breath of inhaled air, all prominent symptoms of the laryngeal disease, must necessarily aggravate the previously existing state of impaired health, and eventually lead to the development of further disease which fixes itself upon the organ most closely connected, anatomically and physiologically, with the one primarily affected, viz., the lungs, the laryngeal disease acting as the direct cause of the lung disease. We thus have established a vicious circle, the one reacting upon the other, and both completing a picture of pain and suffering rarely exceeded in our experience.

The influence of laryngeal ulceration upon the general health is again very markedly evidenced by those cases in which a foreign body becoming lodged in the upper air-passages gives rise to ulceration followed by greatly impaired health, with emaciation and eventually death from this cause or concurrent lung disease.

Among the conditions under which laryngeal phthisis may develop are enumerated the tubercular and scrofulous diatheses, malaria, and syphilis.

The intimate anatomical and physiological connection between the larynx and lungs is sufficient to explain why a very large preponderance of cases of laryngeal phthisis occur in connection with the impaired state of health which attends chronic lung disease. Syphilis is included among the causes, and by this is meant more properly what has been termed syphilitic asthenia, viz., that condition of markedly impaired health we sometimes meet with as the result of infection, in which all specific manifestations of the disease have disappeared. That in this condition laryngeal phthisis may develop, the writer entertains little doubt, having seen such cases in which the progress of the disease and the character of the ulceration in no way resembled the more specific disease, but presented all the features of the ordinary laryngeal phthisis as described further on.

Many writers in treating of the disease describe the first stage as one of anæmia of the larynx. This condition is not a rare one; and while it may, in many cases, exist before laryngeal phthisis, and perhaps excite suspicion, yet it does not point directly to the disease, and presents no features by which we can with

any certainty recognize the threatened danger. There is therefore no sufficient reason for considering it a stage of the disease.

The first stage is that of pyriform thickening of the mucous membrane covering the arytenoid cartilages and the interarytenoid commissure. This thickening is peculiar and characteristic. The contour of the cartilages is completely masked and concealed by a thick, club-shaped swelling, while the commissure bulges out in such a manner as to present a rounded mass anteriorly, which oftentimes interferes with the approximation of the cords, while at the same time it extends upward so as to reach nearly to the level of the cartilages and fills up the normal notch between them. The mucous membrane is reddened throughout the larynx, and presents a moist, boggy appearance, especially over the swollen arytenoids, where it is covered with mucus or muco-pus.

The second stage is that of infiltration of the epithelial coat of the mucous membrane. In this stage we first notice what constitutes a prominent feature of laryngeal phthisis, viz., an excessive cell-proliferation. There appears on the surface of the membrane a small whitish-gray patch slightly raised above the surface, and seemingly an infiltration of its epithelial layer. This occurs in a majority of cases on the laryngeal face of the arytenoid commissure. Its next most frequent site is one of the ventricular bands, and then indifferently in other portions of the organ. These patches may present themselves in groups when they are very small, or they present themselves singly, when they may attain a considerable size. Their duration is very limited, as they rapidly run into—

The third stage, which is the stage of fully developed ulceration. This change the writer has watched in several cases, and has seen the grayish patch gradually change from an apparently quiescent state to one of active discharge. The superficial layer of epithelium being thrown off and new cells being produced, they gradually degenerate into pus cells; the surface of the formerly gray patch becomes yellow in color, the discharge becomes purulent in character, and the ulcerative action becomes established. The ulcer extends by extending its margins, and also by attacking and eroding the parts beneath, and the waste of tissue commences which gives name to the disease. The ulceration may be small, or cover a comparatively large surface. It may be made up of a number of minute points of ulceration, as most frequently occurs when the disease attacks the epiglottis, or there may be several large ulcers distributed in different parts of the larynx.

In this stage we notice more prominently the excessive cell-growth which characterizes the disease. While the destructive ulceration goes on we find developed, sometimes on the ulcerated surface, but more frequently on its margins, small, pointed, warty growths, which may be so extensive at times as almost to conceal and overshadow the ulcerative process; they are very soft, pliable, and easily removed. The error is sometimes committed of picking them off with the forceps, but experience generally teaches the wisdom of letting them alone—certainly until the ulcerations have been entirely healed.

During the second stage often, but far more frequently during the third stage, there may occur a development of the disease of most serious import, in that it not only increases in a marked degree the sufferings and distress of the patient, but also renders the prognosis very much more grave. This consists in the occurrence of an acute follicular inflammation, involving the mucous membrane of the epiglottis,

expending itself mainly upon the follicles so richly distributed about the crest, or it may attack the arytenoids. Its onset is characterized by the sudden pouring out of an exudation into the follicles of the same character probably as that which occurs in the second stage of the catarrhal form of the disease, as before described; but in the one case it infiltrates the epithelial layer of the membrane, while in the other it is deposited in and distends the follicles. It occurs with great suddenness and without warning, a few hours often being sufficient for its development. An examination of the parts at the onset of this form of the disease shows the epiglottis swollen, and the mucous membrane in a state of active acute inflammation; the crest is rounded and thickened, and on the surface of the swollen membrane are seen minute projecting points thickly distributed, of a pearly white or gray color, and slightly clouded, as if seen through a diaphanous covering. The appearance resembles very closely that of a tonsil in a state of acute follicular inflammation in which the morbid condition is probably much the same, with the exception that in the case of the tonsil, the follicles being so much larger and more capacious, the projecting gray points are far more prominent and larger. The subsequent progress of this form of the disease is marked by the breaking away of the covering of the follicles, the purulent degeneration and discharge of its contents, and the formation of a minute point of ulceration at its seat, which by a slow process extends its margin until it coalesces with others; and finally, we may have the whole crest of the epiglottis and a portion of its posterior face involved in a sluggish and slowly destructive process of ulceration; the surfaces become clogged and covered with a dirty-looking, grayish muco-purulent discharge. This condition constitutes what is usually termed the epiglottic form of the disease, and is unquestionably laryngeal phthisis; but whether what has been described as the first stage is one and the same disease with this form, may be questioned by some. Having carefully observed a number of cases which, resisting efforts to arrest the disease, passed progressively through all these stages, the writer holds firmly to the conviction that they are one and the same disease, and one of the main objects of this paper is to urge the importance of recognizing this fact; and hence, the imperative duty of making every effort to arrest it in its early stages, before the later and more intractable form of the disease has set in.

The other appearances which we meet with are secondary and dependent upon the ulceration, such as: acute catarrhal and phlegmonous inflammation of the mucous membrane lining the larynx, and not involved in the ulcerative action; œdema of the loosely-attached portion of the mucous membrane, or the ary-epiglottic folds, and the laryngeal face of the epiglottis; and perichondritis and necrosis of the cartilages.

Subjective Symptoms.—As the above described conditions develop, the subjective symptoms become prominent: these are pain, cough, difficult and painful deglutition; hoarseness, if the cords are affected; aphonia, if the thickened condition of the arytenoid commissure prevents their approximation.

In the first stage the symptoms are not prominent; there is an irritated condition, with a sense of prickling or tickling in the throat, and there may be some pain in swallowing, due to pressure on the filaments of nerves distributed in the swollen parts. As the disease progresses we have the severe and oftentimes exquisite pain due to the pressure to which the parts are subjected in the movements of respiration, phonation,

and especially in deglutition. If the epiglottis is involved the subjective symptoms become greatly aggravated, the pain and difficulty in swallowing become oftentimes most acute, and even the movements of the larynx in respiration or talking become a source of extreme suffering. The food is often regurgitated, and any attempt to swallow food or drink is made with reluctance, on account of the exquisite pain caused by the act; the additional element of pain being due to the mechanical pressure of the bolus of food upon the inflamed surface.

Diagnosis.—In the later stages of the disease this is not difficult. The disease, above all others with which it may be confounded, is tertiary syphilis of the larynx, in which we have the rapidly destructive ulceration, the sharp-cut edges, the excavated surface covered with bright yellow pus, the absence of the warty growths which characterize phthisical ulcers, and especially the areola of red, angry-looking mucous membrane which surrounds it, with the general condition of the patient showing no marked evidence usually of impaired nutrition. In laryngeal phthisis, on the other hand, we have an essentially chronic process of ulceration; the edge of the ulcer ragged and irregular, but not excavated; the surface of the ulcer not markedly depressed, and oftentimes raised above the surface in parts by the excessive cell-proliferation; the absence of the inflamed areola, and the general condition of the patient, always in bad health, and, in a large majority of cases, this due to commencing or existing pulmonary disease; add to this the one subjective symptom of pain which is characteristic of laryngeal phthisis almost without exception, and which is very rarely met with in syphilis, and the differential diagnosis is made comparatively easy.

With lupus, carcinoma, and the various neoplasms which are met with in the larynx, the disease under consideration need rarely be confounded.

But while the diagnosis is not difficult in the later stages, the question becomes an extremely important one whether we have any certain means of recognizing the disease in the first stage, for the writer is confident that when early recognized it is in our power, in certainly a very large majority of cases, to arrest its further progress. The condition described as the first stage of the disease, viz., the club-shaped arytenoid cartilages and the pyriform thickening of the commissure, is believed to be pathognomonic of laryngeal phthisis, and is found in no other disease. This condition the writer has never yet seen except in this disease, or where the diagnosis has not been fully confirmed by the subsequent history of the case, or by other symptoms elicited at the time confirmatory of the diagnosis.

Discarding, then, the old teaching that laryngeal phthisis is a manifestation of tuberculosis, but considering it as a separate and distinct disease, manifesting the symptoms and appearances above noticed, into which a simple laryngeal catarrh may develop, provided there exists the additional impulse toward it of a markedly depraved condition of the general system, due to the tuberculous, serofulous, or syphilitic diathesis, malaria, anæmia, Bright's disease, or any of the blood conditions which weaken the resisting power of the system, the deduction is obvious; if in any of these conditions subjective symptoms arise of laryngeal trouble, it is of the highest importance that a most careful examination be made, and the case watched with additional care; if nothing more than laryngeal catarrh exists, it should be treated by measures especially directed to the parts, in addition to the measures resorted to for the correction of the general habit;

for there can be little doubt that there is an additional danger in the catarrhal inflammation of the development of the disease which we are considering. If there exists the condition described as characterizing the first stage of laryngeal phthisis, there is all the more reason for instituting immediate measures for arresting its further progress.

Prognosis.—This, of course, depends mainly on the success of treatment, and is sufficiently noticed by the record of cases appended below; but, in its special relation to lung disease, it seems to the writer that there is a misconception on the part of many authors. We are usually taught that an improvement in the pulmonary symptoms is attended by an aggravation of the laryngeal symptoms, and *vice versa*. This is but a partial statement of the case. In a given case of laryngeal phthisis, occurring in connection with chronic pulmonary disease, a sudden aggravation of the lung disease may be attended with an apparent amelioration of the subjective laryngeal symptoms. How this is so it is difficult to understand. Possibly the increased morbid action in the one organ may act as a derivative from the other; but that anything more than temporary relief of subjective symptoms occur is improbable. And the same may be said of the converse. But these changes and interacting improvements occur entirely outside of, and independently of, any therapeutic measures. In the experience of the writer, any improvement in the laryngeal ulceration, which is due to direct local treatment, is not followed by, or attended with, any aggravation of the lung trouble. On the contrary, the general condition has improved, the lung symptoms have improved; and, in several cases, there has been detected unquestionably very decided amelioration of the lung disease, as shown by physical examination. Certainly in no case has it been possible to trace any direct connection between an aggravation of the one disease and an improvement in the other. In the earlier stages the disease is curable in probably a majority of cases. And even after the occurrence of extensive ulceration and destruction of tissue the writer has seen cases recover. The occurrence of the follicular ulceration, described as attacking the epiglottis, renders the prognosis very grave. And in a majority of these cases the only hope is to relieve somewhat; this can be accomplished in most cases.

Treatment.—This consists of four steps, which are regarded as of importance:

First. The thorough cleansing of the parts preparatory for the more special application.

Second. The application of such mild astringents, alteratives, or resolvents as may be indicated.

Third. The application of an anodyne to relieve pain or irritability, and to correct any irritation caused by the previous remedies.

Fourth. The application of iodoform as a specific in its action on ulcerations of mucous membranes.

The cleansing is best accomplished by one of the solutions given below, preference being given to the first.

℞. Acidi carbolic, cryst. ℥xij.
Sodæ bicarb.,
Sodæ biborat., āā gr. xxiv.
Glycerinæ. ℥i.
Aque rosæ, ad. ℥ viij. M.

℞. Sodæ salicylat. gr. x.
Sodæ biborat. ℥i.
Glycerinæ. ℥i.
Aque rosæ, ad. ℥ viij. M.

This is best applied by the Sass spray tubes with the compressed-air apparatus, the pressure being about 15-20 lbs. The tongue being protruded, and held, thus lifting the epiglottis and uncovering the laryngeal cavity—the patient being directed to sound in high key A—the point of the tube is passed beyond the crest; and the pressure being let on, the cavity is flooded with the spray before the reflex spasm has an opportunity of shutting off the parts. This should be repeated several times, until the ulcerated surfaces are thoroughly cleansed, and the fact ascertained by inspection with the mirror. This cleansing should always be grateful to the patient; and if there is any pain or irritation caused by it the solution used should be reduced in strength, or changed. Care should always be exercised, of course, to avoid wearying the patient. If nausea or vomiting is caused, the sitting should terminate for the time.

After the parts are thoroughly cleaned an anodyne solution may be used, although this is not always essential. But if during the sitting any of the applications cause pain, an anodyne or soothing application should be thrown in to relieve it. Of these a 5-10 gr. solution of morphine may be used, with the addition of sodæ carb., or potass carb., to give it an alkaline reaction. A small portion of mucilage acacia added may increase its soothing effect.

The next step in the treatment consists in the application of an astringent. In the order of preference, these may be used: zinc sulph., gr. x.— $\bar{3}$ i.; arg. nitrat., gr. iij.—v. to $\bar{3}$ i.; zinci chlorid., gr. iij.— $\bar{3}$ i.; tannin et glycerin., $\bar{5}$ i.— $\bar{3}$ i.; liq. ferri persulph., \mathbb{M} xx.— $\bar{3}$ i. The selection of the special astringent being governed somewhat by the effect and tolerance.

Finally, there should be applied iodoform to the surface of the ulcer. This is used for its specific action; it is easily borne, rarely gives pain, and its effect in many cases is most satisfactory. The formula generally employed is as follows:

R.	Morphine.....	gr. x.	
	Tannin.....	$\bar{5}$ ij.	
	Iodoform.....	$\bar{5}$ vj.	M.

Sometimes the saturated solution in ether is used, \mathbb{M} xl.— $\bar{3}$ i., but the powder is generally preferable. This application is made with the powder-blower, first suggested by Dr. A. H. Smith, so constructed as to deposit a smooth, even layer of powder on the surface, thus avoiding the objection to the ordinary Rauchfuss insufflator, and instruments of that class which project the powder in mass, and often do harm by their failure to evenly distribute it, and by piling it, as it were, in parts of the organ, thus causing too much irritation. The insufflator of Dr. Smith consists of a small open-mouthed bottle, through the cork of which two tubes are passed, bent at right angles; to one tube is attached a single hand-ball; the other is fashioned to adapt it for the especial application to be made. The powder being placed in the bottle, a single quick pressure on the hand-ball drives a current of air into the bottle, which stirs the powder up into a fine cloud, and drives it out in this state of fine diffusion through the other tube, and deposits it in an evenly distributed thin layer over the parts which it is desired to medicate.

(To be continued.)

DECREASE IN THE NUMBER OF DOCTORS IN FRANCE.

—The number of doctors of medicine practising in France in the year 1866 was 11,251, and that of "officiers de santé," 5,568. In 1877 there were only 10,741 doctors and 3,633 "officers," a reduction of 2,416 in the number of practitioners.

Reports of Hospitals.

THE PHILADELPHIA HOSPITAL.

NOTES OF PRACTICE AND PECULIARITIES OF TREATMENT.

(Reported for THE MEDICAL RECORD.)

WARDS FOR DISEASES OF THE NERVOUS SYSTEM.

The cases found in these wards, which are in charge of Dr. Charles K. Mills, neurologist to the hospital, are chiefly examples of chronic organic disease of the nervous system—hemiplegics from hemorrhage, thrombosis, or embolism; cerebral, cerebro-spinal, and spinal scleroses; meningitis, meningo-encephalitis, and meningo-myelitis; epilepsy, hystero-epilepsy, and hysteria; brain tumors, spinal softening, and the like. Acute cerebral and spinal disorders; neuralgias, peripheral paralyses, local spasmodic diseases, and similar affections, are sometimes, but not so frequently, represented.

ELECTRICITY.

In connection with the wards, a large apartment, known as the *Electrical Room*, has been fitted up. It contains one of Flemming & Talbot's permanent batteries of sixty cells, and a fine faradic instrument from the same manufacturers. The wards are also supplied with portable galvanic and faradic instruments.

Dr. Mills, during the past year, has used electricity with marked success in the treatment of bed-sores, which, in spite of the best of care, are apt to form in cases of spinal and cerebral disease. The "silver-and-zinc-plate" method is the one generally employed, a silver plate being placed over the sore, and a zinc plate (connected by a wire with the silver) on a piece of acidulated chamois skin or paper lint, which rests on the unbroken skin a few inches above. A weak current from the galvanic battery is sometimes used instead of the plates. A silver plate applied to the sore is connected with the negative electrode; an ordinary rheophore, joined to the positive pole, being placed upon the surface near. The s'ance is continued for from five to ten minutes daily. Many cases of chronic ulceration put into the hands of the neurologist for electrical treatment have been cured by the galvanic plates, or the use of the battery current. Electricity is very effectual in stimulating healthy granulations.

Faradization is used in the wards to improve the condition of palsied muscles; and central galvanization is employed chiefly in spinal affections.

METALLOSCOPY AND METALLOTHERAPY.

Numerous experiments in metalloscopy and metallotherapy have been made in the Nervous Wards, only a few of which can be alluded to at present.

In one case of brain tumor with partial anesthesia of the left leg, a small zinc plate applied to this limb in an hour caused a sensation which was described by the patient as being like that produced by the "battery," referring to a faradic instrument. Other metals were tried, but had no effect. The salts of zinc were used without success, iodide of potassium being the only remedy that seemed to help the case.

Some curious results were obtained in a number of cases of marked anesthesia from hysteria and spinal disease, to two of which reference will here be made.

One case was that of an unmarried woman, aged twenty-nine, supposed to be an example of hysterical paraplegia and anaesthesia. On two occasions plates of zinc, iron, copper, tin, silver and gold, of about the same size and weight, were placed on different parts of the body simultaneously; at other times the applications were varied—sometimes one plate, sometimes two or three were used. Many trials were made, the patient being blindfolded, and different locations being selected for the same plate. In five instances the patient picked out the zinc plate in from twenty to forty minutes, saying that she felt under it a sensation which she described as tingling, or as like "pins and needles." Twice she referred similar, but weaker, sensations to the plate of iron, but other metals gave no result.

Sensation was temporarily improved, muscular power was apparently increased; and the anaesthetic limbs bled more freely, on pricking them with needles, after the zinc was applied, until the peculiar sensations described were called forth. This patient was kept upon the use of valerianate of zinc for six weeks—sensation, motion, and her mental condition improving. Subsequently, however, she relapsed.

A second case was that of a man, aged twenty-eight; an advanced case of sclerosis of the posterior columns, with almost absolute anaesthesia of the lower extremities. After carefully testing the condition of sensibility and of the circulation, a small zinc plate was applied to the right calf, and a silver plate of the same size to a corresponding part of the left leg. In thirty minutes he began to have a sensation as if needles were pricking him under the silver plate. Two or three minutes later he had a similar, but weaker, sensation under the zinc on the right limb. The plates were kept on ten minutes, during which time he had four alternations of sensation in the two sides. When the pricking sensation was present under the silver plate it would be absent under the zinc, and vice versa; but it was in each instance much more decided under the silver. On removal of the plates electro-sensibility was decidedly improved. No change of sensibility to the aesthesiometer or state of the circulation was produced. The symptoms in this case were decidedly ameliorated by both nitrate and oxide of silver, but were not permanently benefited by any treatment.

Dr. Mills does not believe that the theory of "expectant attention" will explain satisfactorily all the phenomena which result from metallic applications. Patients do certainly sometimes exhibit metallic idiosyncrasies—whatever may be the explanation. Anaesthesia, even when the result of organic disease, can be temporarily removed by applying pieces of metal. He has observed that two metals will sometimes produce similar effects on the same individual; but, even in these cases, he has always found that one of the two will give rise to more decided sensations, and will be more positively effectual in removing the anaesthesia.

In regard to internal metallotherapy, it is somewhat difficult to arrive at a decision. Irrespective of metalloscopic investigations, the value, in chronic spinal diseases, of the preparations of zinc, silver, and other metals, has long been known. They can also be used with advantage in cases in which no effect is produced by external applications of metals. The salts of silver and zinc will undoubtedly bring about amelioration of serious symptoms in cases in which these metals, when applied to anaesthetic limbs, will be selected by patients in preference to others because of the peculiar sensations which they cause.

MASSAGE AND SWEDISH MOVEMENTS.

Both massage and Swedish movements are employed to a considerable extent, some of the nurses being trained for this work. Massage is found to be of benefit, even in old cases of paralysis, serving to keep up nutrition and temperature, and preventing trophic changes. In neuralgic and hysterical cases it also often proves of great service.

In the same room in which the permanent electrical instruments are kept, are some simple forms of apparatus for the movement treatment, such as a cross-bar adjustable at various heights, a leaning cylinder for exercising the muscles of the trunk, a stool of the proper height and size for sitting movements, and a lounge or couch so hinged as to be capable of being inclined at various angles. The patients are taught to practice movements with or without assistance, according to the nature of the case.

A movement treatment, without apparatus, is also often used. The kinds of movement usually resorted to, without appliances, are the passive, or the duplicated active. Systematic passive movements are employed for the purpose of preventing, as far as possible, atrophy and deformities. Joints are kept in a healthier condition through the agency both of massage and these passive movements. Duplicated active movements are used in those cases in which the loss of power in sclerotic or paralytic patients, for instance, is not absolute. In conjunction with faradization this method of treatment often results in the marked improvement of the paralyzed limbs, palliating symptoms, and improving circulation and nutrition even of palsied limbs.

THE ACTUAL CAUTERY.

The actual cautery, either alone or conjoined with other remedies, is frequently resorted to in the treatment of epilepsy, and of chronic spinal diseases. The ordinary cautery-iron, with a button shaped like the blunt end of an olive, has usually been employed, but recently the hospital has obtained a Pacquelin cautery, in which the vapor of pure benzine is forced by an air-blast upon a piece of hot platinum. Superficial applications to the nape of the neck, or along the spinal column, are made every two or three days. The intervals between epileptic seizure has been extended from days to months by the use of the cautery.

THE TREATMENT OF SYPHILITIC BRAIN DISEASE.

The wards are nearly always well supplied with syphilitic affections of the brain and cord. Iodide of potassium in energetic doses is largely employed. Mercurial inunction has also been extensively tested, and in a few instances with striking results. From half a drachm to a drachm and a half of mercurial ointment is used daily, or every other day, the treatment being persisted in until some effect is produced, or good reasons arise for its discontinuance. Before inunction, the parts to which the ointment is to be applied are well sponged with warm water. Strict attention is paid, at the same time, to diet and hygiene.

TREATMENT OF SPINAL SCLEROSIS.

For the various forms of spinal sclerosis, and particularly for posterior spinal sclerosis, or locomotor ataxia, the salts of silver—the nitrite, phosphate, or oxide—are generally found to be the most efficacious internal remedies. They are used in doses of from one-third to one-half a grain, and are often combined with some bitter tonic, as the extract of gentian or quassia. Electricity, in the form of moderately strong galvanic currents, is also much used; stable currents

to the spine, and labile currents to the limbs being the most common methods of application. Early in posterior sclerosis large doses of ergot are often prescribed.

THE TREATMENT OF CEREBRAL AND SPINAL EXHAUSTION.

Preparations of phosphorus are used in the treatment of cases which show signs of cerebral or spinal exhaustion. A favorite preparation of this substance is the oil of phosphorus of the Prussian Pharmacopœia. This oil is administered according to the following formula, which is also used at the Hospital of the University of Pennsylvania:

R. Olei phosphorati..... ℥xvj.
Olei gaultheriæ..... ℥viiij.
Mucilag. acaciæ, q. s. ad..... fʒj.

M.

Sig. One to two teaspoonfuls three times daily.

The oil of phosphorus itself can be prepared by the following process: "Into five fluid drachms of pure almond or olive oil, contained in a glass flask, drop three grains of transparent phosphorus. Place the whole in a water-bath at 175° F., and agitate until dissolved."

CALABAR BEAN IN DEMENTIA PARALYTICA.

Calabar bean is prescribed in dementia paralytica, cases of which, in the early stages of the disease, sometimes find their way into the Nervous Wards. If not promptly relieved, they are transferred to the Insane Department. Pills of the ext. physostig. venenas, each containing from the one-sixth to the one-third of a grain, are given three times daily, the treatment being persistently continued and the effects of the drug constantly watched. Rest, nourishment, and counter-irritation to the head or nape of the neck are conjoined with the calabar bean.

GENERAL NOTES.

Cannabis indica, hyoscyaminus, conium, morphia, chloral, and bromide of potassium are used to fulfil various indications, such as tremor, headache, sleeplessness, mental symptoms, etc.

APOPLEXY.

In the treatment of the apoplectic state the patients do not stand depletion well. Bleeding is seldom employed. Supporting measures are often found to be necessary to carry the cases successfully through the attacks.

Progress of Medical Science.

GALVANISM IN THE TREATMENT OF SCIATICA.—Dr. Gibney has employed this agent in fifteen severe cases of this disease. Eleven cases were entirely cured, only one of which had a relapse at the end of eight months, under strong provocation. A very strong current was employed; in some instances lively erythema was observed around the electrode, and in two patients an eschar was found after the electrode was removed. No bad effects were found to follow these strong currents. With regard to the direction of the current, Dr. Gibney believes that it is immaterial, though all his cases were treated with the ascending current. In the earlier cases the positive pole was placed over the lumbosacral region, and the negative over the seat of the pain. In the later cases, the positive pole was

placed over the trunk of the nerve at its exit, and the negative over the seat of the pain. It is best not to move the sponges from place to place during one sitting, as the contractions which follow the breaking of the current prove too irritating to the nerve. If the pains are diffuse, it is better to reach the distribution of a single branch at a single sitting. At the next sitting another branch can be embraced in the galvanic current. The sitting should vary from five to fifteen minutes, and should be held daily, or at least every other day. No internal remedies were employed in any of the cases reported.—*Trans. New York Academy of Medicine*, Feb. 6, 1879.

TWO CASES OF SYPHILITIC PARAPLEGIA.—Dr. Buzard gives the following histories of two interesting cases of syphilitic paraplegia. The first was a male, æt. 25 years, who contracted syphilis one and a half years previously. Nine days before admission to hospital he suffered from intense paroxysmal pain in the right ham, at first dependent on motion, and then occurring spontaneously. Upon admission, patient had severe pain between the scapulae, and the back appeared to be stiff. When the second lumbar vertebra was percussed, the right leg was seen to twitch. There were sharp pains around the trunk from the nipples to the hips. The lower limbs were analgesic and anæsthetic, more markedly on the right side. The right limb was almost completely paralyzed, the patient being merely able to move the ankle-joint slightly; the power of the left leg was not materially lessened. Reflex excitability was retained. There was paresis of the bladder; the muscles of both legs reacted well to faradism. Pulse 88, temperature 98.4 F. Iodide of potassium was given in doses of ten grains (increased in a few days to thirty), three times a day; the spine was rubbed with mercurial ointment, until the gums became tender. The patient began to improve almost immediately, and on the thirty-sixth day he was up and walking very fairly, but sometimes suffered from a cramp in the back of the right thigh and slight pain in the hypogastric region. The right leg seemed as strong as the left, and there is no defect of sensibility. He was discharged cured on the fiftieth day. This is evidently a case of more or less circumscribed inflammation of the spinal meninges, in the lower dorsal portion of the cord, and affecting chiefly the right half. The meningitis was probably gummatous, and involved especially the internal surface of the dura mater.

The second patient was a female, æt. 29 years, married. She entered the hospital suffering from much loss of power and numbness in both lower limbs, especially the right. She had been attacked three months previously with numbness and formication in the feet, and these symptoms extended upward until the arms became involved. The patient had a feeling as of a tight band around the waist, and suffered from constipation and some atony of the bladder. The left pupil was somewhat smaller than the right, and irregular; eyesight was normal. The ophthalmoscope showed, in the right eye, evident remains of disseminated choroiditis (atrophic and pigmented spots), and, in the left eye, old adhesions of the iris and opacities of the vitreous body. Ten grains of iodide were ordered, three times a day. Within two weeks she had lost the feeling of tightness around the waist, the numbness in the legs, and the delay of the bladder. The hands were still very numb and dead, so that she could not use a needle or pin. The dose was increased to fifteen grains, and at the end of a month she was perfectly well.

Constitutional syphilis was proven by the ophthalmoscopic appearances and by the immediate influence of the iodide. The most probable suggestion appears to be that the lesion was an alteration of blood circulation in the membranes of the cord. The mode in which the affection travelled upward reminds one of acute ascending paralysis, but the length of time occupied in the process and the eventual recovery exclude this explanation. We cannot at present satisfactorily explain the manner in which constitutional syphilis brings about such an altered condition of circulation as we suppose to have been present in this case. It is not, perhaps, extravagant to suppose that there may be a thickening of the walls of minute blood-vessels (with a consequent diminution of their calibre), which gives way to specific treatment.—*The Lancet*, April 5, 1879.

HYDROCELE OF THE FEMORAL CANAL.—Dr. Osborn reports the following as a case of hydrocele of the femoral canal (in other words, a process of peritoneum projected from the general peritoneal cavity, and not a hydrocele of a femoral sac), because, after withdrawal of the fluid no impulse was obtainable on the patient's coughing, nor was there on manipulation any sensation of there being a rupture in the femoral canal.

Caroline S., æt. 52 years, first noticed a swelling in the right groin eighteen months ago; is quite sure that the swelling did not commence during or after a fit of retching. When first noticed it was the size of her little finger, rather elongated, and like a swollen vein. For fourteen months the tumor produced no inconvenience, but four months ago it began to grow much larger, and became very hard. She states that a physician then reduced a portion of the swelling, as it again went back to its original size. Two weeks ago it again became much larger, and very painful.

On examination a tumor was found over the saphenous opening about the size of a bantam's egg, smooth, fluctuating, and transparent by transmitted light, with some hard nodules below and at the inner side. Taxis succeeded in reducing part of the swelling, but the same evening it was again as large as at first. November 8th.—Cyst tapped, and about nine drachms of a clear, pale yellow serous fluid withdrawn. The hard nodules could now be diagnosed as glands, since similar indurated lumps were felt about the opposite saphenous opening. A pad of lint was bound on by a spica bandage to keep the surfaces of the sac in contact. November 9th.—Cyst found to be still empty; bandage reapplied. November 19th.—Patient got up, wearing a femoral truss, having been confined to her bed during treatment. December 5th.—No accumulation of fluid in the cyst.—*The Lancet*, April 5, 1879.

A URINE-THERMOMETER FOR GYNECOLOGICAL PRACTICE.—Dr. Otto Küstner, of Jena, describes an ingeniously arranged instrument for measuring the temperature of the urine in gynecological practice. The instrument consists of a silver female catheter, which contains in its lumen a self-registering thermometer. The catheter tapers sharply below the point to which the bulb of the thermometer reaches, and in addition to the usual eye at its vesical end, possesses another near the external end for the escape of the urine. The thermometer is firmly soldered to a silver top which fits closely into the outer end of the catheter; this top, with the thermometer attached, can be removed at will. The space left between the thermometer and

the wall of the catheter is about equal in area to the lumen of the tapering end of the catheter, so that the urine can pass out freely, bathing the thermometer in its course, and escaping in a stream from the external eye of the catheter. When the instrument is introduced into a moderately filled bladder, the column of mercury in the thermometer attains its maximum point in from eight to fifteen seconds according to the rapidity with which the urine escapes, the rapidity of the flow of urine in turn depending on the usual causes, viz., the degree of distention, the action of the abdominal muscles, the age of the patient, etc. The average quantity of urine that escapes through the instrument in fifteen seconds is about sixty c.cm. (about two ounces), although this, of course, is subject to many differences. The temperature of the body measured in the urine in fifteen seconds and less with this instrument corresponds very closely with the temperature obtained with the same thermometer when left in the vagina for five minutes, the difference, when any exists, being at most 0.1–0.15 of a degree (C.). This fact was verified by a large number of experiments. Hence Dr. Küstner claims that his instrument, against the use of which in gynecological practice no objection can be raised, presents the most certain and rapid method of measuring the temperature of the body.

Oertmann was the first to suggest the measurement of the temperature of the urine as a means of determining the temperature of the body. His method, however, which consisted in urinating on the bulb of a thermometer, was intended only for the use of men, and moreover only for men who pass larger streams of urine. Dr. Küstner endeavored to adapt it to use in the cases of women by introducing a catheter into the bladder and allowing the urine to flow from it over the bulb of a thermometer, but the results were not satisfactory. The temperature of the urine obtained in this way was, it is true, pretty constantly from 0.3–0.5 (C.) higher than the axillary temperature taken at the same time, but still greater or less differences often occurred, the above relation being sometimes reversed. These differences were perhaps partly due to radiation and absorption of heat by the catheter. Moreover, the time required for the mercury to attain its highest point was from thirty to forty seconds. On the other hand, the advantages claimed for the new instrument in measuring the temperature of the urine in women are: the rapidity with which the measurement is taken, the small quantity of urine required for it (even if the patient urinated half an hour before there will be enough urine in the bladder for the purpose), the practically absolute uniformity of the results with those obtained in the vagina, and the convenience of application.—*Centralblatt f. Gynäkologie*, Feb. 15th.

MASSAGE OF THE TONSILS.—M. Quinart describes, in the *Archives médicales belges*, a method of treating hypertrophy of the tonsils that has proved very successful in his hands. The method, which is only applicable after the inflammatory period has passed, consists in massage of the gland, and is carried out as follows: He covers his index finger with alum, introduces it into the mouth, and brings it to bear directly on the tonsil, which is manipulated, with gradually increasing force, over as great an extent of its surface as can be reached. The operation is at first painful and disagreeable; but the discomfort is readily allayed by an emollient gargle. After a few repetitions, it ceases to be painful, and the patients readily learn to practise it themselves.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

W.M. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, May 17, 1879.

AMERICAN MEDICAL ASSOCIATION.

THE meeting of the American Medical Association at Atlanta, Ga., differed in no very notable respect from many of its more recent predecessors. In fact, the machinery of the organization is so complete, and the provisions for the disposal of almost any amount of business are so perfect, that it would be an exception to have the usual routine seriously disturbed. Of course new questions come up for discussion each year, but they are now, contrary to what it was in former times, disposed of in a dignified and satisfactory manner. During the present session the latter was the case, with scarcely a single exception, the Association doing itself honor by its different recorded votes.

The question of teaching homœopathic students came up as an amendment to the Constitution, under the rule, and was very candidly presented by the Chairman of the Council, with the ultimate result of postponing action for another year. It could hardly have been supposed that the Association would be prepared to commit itself in favor of the amendment, inasmuch as such action would be in conflict not only with common sense, but with the individual rights of students and teachers, and the chartered privileges of all institutions of learning. The regular medical colleges have no more right to deny instruction to any one who is capable of receiving it and who is willing to pay for it, than have any other institutions of learning. The trustees and professors of any of these schools have no more right to impose any conditions as to the subsequent use of instruction thus given, than have any other venders of raw material. As well might the lumberman refuse a sale for his logs, unless the same were to be subsequently fashioned after a particular model which he might prefer, and be subjected to a use which, from his standpoint, was the only proper one. It must be admitted that, from a purely selfish aspect, the question has its serious objections, but when we elevate it to a principle

there is but one view of the matter to be entertained—a view which, we are happy to state, was taken by the Association.

The scientific element of the Association was, perhaps, not as marked as on previous occasions, although many of the papers read before the sections were very creditable productions, and called forth interesting discussions. The attendance, under the circumstances, the meeting being held in such a remote locality, may be considered to be unusually large. There was to be noticed a want of system in the management of some of the sections which interfered somewhat with their usefulness. This is not so much the fault of the committee, as it is the almost inevitable result of placing new men upon it each year. What is wanted is experience in arranging the machinery, and this can only be acquired by continuing one or two on the committee for two or three years at a time. This, possibly, cannot be done, as the Association meets from year to year in widely separated localities, and it being necessary that two or more members shall be residents; still, its practicability is worth considering in view of the good results to be obtained.

The choice of the President for the coming year will doubtless meet the approval of the majority of the profession of this country and abroad. Dr. Sayre has fairly won the high distinction which has been conferred upon him by his fellow-countrymen. Not only has he been an active, efficient, and successful worker in the ranks of the profession, but a punctual attendant of the meetings of the Association, and a constant and valued contributor to its Transactions.

The selection of New York as a place for the next meeting is a good one, and our friends from the different sections of the country will receive that return of hospitality which many of the delegates have received from their hands for many years past.

THE DWIGHT INQUEST.

THE profession has again been represented on the witness-stand, and with the not unusual result of displaying little more than the imaginative resources of medical experts, and the limitations of medical knowledge.

Last November, Col. Dwight, of Binghamton, N. Y., after quite a prolonged illness, in which he suffered chiefly from vomiting, abdominal pains, and great prostration, rather suddenly died.

He had been treated for malarial poisoning, and was supposed to have died from a congestive chill. He had previously insured his life for more than a quarter of a million in various companies, and, as there were rumors about suicide, a post-mortem was authorized. This was very carefully made by Dr. Delafield, in the presence of a number of other medical men. No evidence of poisoning or of violent death was found, in spite of a long and minute examination. Nor were there any notable lesions dis-

covered. There was some hemorrhagic pachymeningitis, the lungs were congested and œdematous, the heart flabby, containing a small amount of blood; the spleen was enlarged, and there was a chronic gastritis. The cause of death was given by Dr. DeLafield as paralysis of the heart; by Dr. Burr, the attending physician, as congestive chill. We are not informed as to whether there was a disagreement between these physicians; but, at any rate, it was unanimously agreed that death occurred naturally, and all the physicians signed the report of the autopsy to that effect.

Last April, instigated by the insurance companies, the body was exhumed and another autopsy held on it, it having been claimed that a sufficient cause of death had not been found by the previous one. The bright and shining light in this connection was Dr. Swinburne, a gentleman who had been present at the previous examination and assented to its conclusions. He, however, on this occasion, noted a crease in the neck of the deceased, which was, he thought, made by a cord, and the theory was presented that Col. Dwight had tied this cord around his neck, then looped it over the scroll-work of his bedstead and hung himself. His wife, attendant, and others, who were with him when he died, or shortly before, conceived of course at the performance. This crease in the neck had been carefully examined at the first autopsy, and it was agreed to have been simply a natural one, the deceased having been a full-faced, fleshy man. Under some fresh stimulus to observation, however, this innocent marking made evidence of the triple crime of murder, suicide, and robbery.

The strength of the case for the insurance companies lay chiefly in the fact that Col. Dwight had insured himself heavily while possessing, it was thought, no means of paying the premiums, and further, that no very clear evidence of the primary cause of death was found. The theory of congestive chill was not very strongly supported by the evidence, and only negatively so by the autopsy. Pernicious ague is often, indeed, a boon to those perplexed by obscure and malignant symptoms, as well as a scapegoat for inefficient observation. It is sometimes equally difficult to swear that it has or has not existed, and perhaps on this account it served a tolerable purpose in the present case. The other statement, however, that the patient died from paralysis of the heart, was a senseless and inadequate one as far as explaining the event is concerned. Nevertheless, the report that the autopsy revealed this to be the cause was generally circulated, and the evident insufficiency of such a theory assisted in discrediting the value of the examinations. It was at these two weak points that the insurance companies made their attack, and they succeeded in attracting much attention to their claims. The theory of strangulation, however, which they put forward to account for the death, was ridiculous to the point of imbecility. They lost their cause, and justly, but not so much

from the strength of their opponent's case as from the weakness of their own.

The whole affair reflects anything but brilliancy upon the profession and the performers. The spectacle of an intelligent jury listening for days to expert testimony in regard to a fold of adipose tissue was not an impressive one, though it may have had some terrors for the corpulent. It serves, however, to point the moral, which we have drawn before, of the bad results coming from the present system of calling expert witnesses. Ingenuity and imagination seem to be now the most essential qualities of those summoned in this capacity?

CONTROL OF CONTAGIOUS DISEASES BY THE BROOKLYN BOARD OF HEALTH.

AN account of what has been done in the above direction has been given by Dr. J. H. Raymond, in the "Proceedings of the Kings County Medical Society" for May. Until recently the certificate of a physician was enough for the readmission of children, who had been suffering from a contagious disease, to the city schools. Now, however, a certificate from the Health Department is required, and much greater security is thus obtained. As soon as a case of contagious disease occurs it is reported to the Central Board. Every twenty-four hours a list of these cases is made out and sent to the teachers of the eighty schools in the city, so that if any of their scholars are included, they may be kept from school. In addition, sanitary inspectors visit these cases as soon as reported, and they send a second notice of the case to the teacher of the school to which the child belongs. This arrangement secures additional protection, and makes it impossible for any case to go unnoticed. Further regulations require the room in which the sick person has been living to be fumigated as soon as the sickness is over, this fumigation being generally done by burning sulphur in it—about one pound to a thousand cubic feet of air-space. The child is not allowed to return to school until seven days after the last exposure. The means for protection are thus very completely arranged, and seem to have been carefully carried out. No statistics are given showing the practical results of these measures, and it is, probably, too soon to judge of how much good they really do in diminishing the disease.

MALPRACTICE.

THE medical profession has again been called to answer in court for doing its duty. In 1871 one of the surgeons of the Manhattan Eye and Ear Hospital, in this city, after consultation with both of his colleagues, advised an operation for chronic glaucoma. The disease had progressed so far when the patient entered the hospital that vision was reduced to the discernment of large objects with the right eye, and to only one-half ordinary visual power with the left.

The necessity of an operation was agreed upon by the three gentlemen, then surgeons of the institution, and was performed *secundem artem*. No accident occurred during the operation. Two weeks after the patient left the hospital with vision exactly the same as when she entered it. In a few days after her dismissal inflammation developed, and she returned to the hospital with the right eye nearly destroyed, and the left much more impaired than when she was discharged. Another operation was advised upon both eyes. She declined, however, to have it upon but one. This operation was performed without effect, and the patient became blind. It should be stated that the patient was not a pauper, her husband being a man well able to pay for any surgical advice or operation. This fact was unknown at the time of her treatment, and she was treated simply for her board at the rate of *ten* dollars a week. Six years after she instituted a suit against the hospital for loss of her sight, claiming that there was nothing whatever the matter with the left eye when it was operated upon, and that there was an agreement with the surgeon that only the right eye should be interfered with. She brought suit for \$50,000 damages. The case came on last week in the Supreme Court, Judge Lawrence presiding, and is now in progress. It turned out upon the trial that the patient was not entitled to gratuitous treatment, and that her husband was a man of means. It was also proven that her husband was present at the operations upon the two eyes, that he made no comments upon the fact that both were being operated upon, and, although in the hospital daily for two weeks, that he never complained to the surgeons, or to any of the authorities, with regard to the operation upon both eyes instead of one; nor did he make any complaint of any kind. The hospital attempted to secure a dismissal of the complaint upon the ground of having secured competent surgeons, and that the directors were not liable for want of skill upon the part of their servants. The judge regarded this as an important question, was not quite decided in his own mind upon the point, but overruled it for the present. The hospital then proceeded to show the character of its surgeons by distinguished general practitioners, and also the facts as to the operation, to which allusion has been made. It was proven that glaucoma, especially chronic glaucoma, is a disease which almost inevitably ends in blindness; that surgical interference affords the only hope of relief; that it is readily diagnosed with the ophthalmoscope, and that it cannot be positively detected without the aid of that instrument.

The prosecutor gave a very graphic description of the letting out of his wife's eyes—of which he made no complaint at the time of the operation—of seeing the eyes running out upon the cheek, a scientific statement which seemed to make a deep impression upon the jury. It is hardly worth while to seriously com-

ment upon such an outrage as this, for the medical profession is well aware that they are subject to just such persecution. We need to instruct the lay mind until it can comprehend the fact that surgeons do not wilfully put out eyes; that that is reserved for gougers, and that there are diseases which end in death and deformity in spite of the most skilful care. For the credit of our craft it should be stated that there was no discrepancy of opinion, among all the oculists called, with regard to the nature of the affection and the propriety of the treatment, and that the character of the surgeons of the institution for care and skill was fully vindicated by their professional peers in other branches of the profession. We have simply recited these facts in order, if possible, to aid in uniting the profession in attempting, by influence and legislation, to protect us from similar assaults. The case is still on. Up to this time no medical testimony of any kind has been brought forward to sustain the charges made against the hospital. Next week we shall be able to present the charge of the judge and the verdict of the jury, which, we feel sure, will interest our readers.

Reports of Societies.

AMERICAN MEDICAL ASSOCIATION.

THE THIRTIETH ANNUAL MEETING,

Held in the City of Atlanta, Ga., May 6, 7, 8, and 9, 1879.

TUESDAY, MAY 6TH.—FIRST DAY.

THE Association met in De Give's Opera House, and was called to order at 11 A.M., May 6, 1879, by the President, THEOPHILUS PARVIN, M.D., LL.D., of Indianapolis, Ind.

Prayer was offered by REV. D. W. GWIN, D.D.

The address of welcome was delivered by DR. JOSEPH P. LOGAN, Chairman of the Committee of Arrangements.

MEMBERS BY INVITATION.

The following gentlemen were elected members by invitation: Drs. A. W. Griggs and J. E. McMillen, of West Point, Ga.; C. B. Ridley, of La Grange, Ga.; R. C. Worth, of Decatur, Ga.; J. Dickey, of Thomas-ton, Ga.; J. C. Walker, of Wilmington, N. C.; W. J. Harrell, of Bainbridge, Ga.; G. Ellis, of Boonville, Mo.; J. B. Roberts and H. N. Hollifield, of Sandersville, Ga.; B. W. Toole, of Talladega, Ala.; R. C. Eye, of Augusta, Ga.; J. T. Slaughter, of Villarica, Ga.; George Homan, of St. Louis, Mo.; and A. M. Owens, of Evansville, Ind.

PERMANENT MEMBERS.

The following gentlemen were elected permanent members: Drs. J. M. Johnson, H. L. Wilson, J. F. Alexander, C. Pinckney, Jas. A. Gray, D. H. Howell, W. Dean, H. B. Lea, R. B. Ridley, and J. T. Johnson, of Atlanta, Ga.

General F. A. Walker, of Washington, D. C., was invited to take a seat upon the platform.

LETTERS FROM ABSENTEES.

Letters were read from Drs. H. I. Bowditch, of Boston, J. C. Hutchinson, of Brooklyn, and H. R. Storer, of Newport, regretting their inability to be present at the meeting of the Association.

ANNUAL ADDRESS OF THE PRESIDENT.

DR. THEOPHILUS PARVIN, of Indianapolis, then delivered his address, which was a most scholarly production, and was listened to with profound attention. The following is a brief abstract: After referring to the great subjects of human study—science, literature, philosophy, and theology—he passed to a department of medicine not limited by scalpel, test-tube, and microscope. Knowledge of the intellectual and of the moral nature of man was just as essential to the thoroughly furnished physician as any knowledge of the merely material organism.

WHY MEDICINE?

At the very outset of our inquiries was, Why did medicine exist? What reason for it? It was born of human sympathy; it sprang from the heart of man, and was an evidence of humanity; it lived because it could live; it had a right to live. Medicine came in response to the cry of human suffering. Pain was the first lesson in the book of evil which most human beings read in such bitterness of sorrow. The problem of physical suffering,

THE MYSTERY OF PAIN,

was then considered, and Alexander Bain's definition given: "Pain expresses an ultimate fact of human consciousness, a primary experience of the human mind, resolvable into nothing more general or more fundamental than itself." But why was that fact? The most obvious reason for the existence of pain was that which the word itself signified. Reference was then made to the various uses of pain. Even with the various utilities of pain, it still must be referred to as often a mystery—more was hidden than revealed.

Greater than the mystery of life was

THE MYSTERY OF DEATH.

Here reference was made to what had been written regarding this mystery by Bacon, Fontenelle, Maudsley, Johnson, and others.

WHAT IS MAN?

But what was man, thus made subject to disease and death? In the human ovum, which neither chemistry nor the microscope could distinguish from the common mammalian ovum, there dwelt physical potentialities, species, races, family, individuality. In that ovum there was the assured promise of all that made a perfect organism. The author then referred to

FACTS OF HEREDITY,

intellectual, moral, and pathological. Passing the evolution of the various parts of the human organism, the transition to the external world, and the shades of speculation as to when, where, and how man originated, he passed to the consideration of

MAN AS HE NOW IS,

"the heir of all the ages." The general belief of mankind was that his nature was dual, and expressed by the terms *body* and *mind*.

MAN AS A MATERIAL ORGANISM.

The assertion of human duality included two positions: first, man had a physical organization; and, second, a mind. He first considered man as a material organism. He did not believe that the phen-

omena of living beings could all be referred to physico-chemical laws; but we must, with Beale, "accept the idea of vital power as being super-physical, and with that idea its correlate, a living Creator of such power. Passing the perfections of the human body, the speaker reached the second proposition:

"THE COMPLETE CONCEPTION OF MAN INCLUDES MIND."

Had physiology reduced the facts of intelligence to the phenomena of matter? Certain utterances seemed to indicate that some answered the question in the affirmative. Many of the utterances, however, were open to criticism, if not to unequivocal rejection. The speaker then noticed some of the difficulties which were obvious in all schemes of mental physiology, or effort to interpret phenomena of mind by physical facts. The identity of corporeal and of spiritual phenomena was an affirmation which ought to be assigned to the list of impossible hypotheses. The speaker then passed to

THE PROBLEM OF TELEOLOGY,

which commended itself especially to our profession. It was not set aside by the development theory; nor was it to be cast aside because of its abuses. Time was lacking to refer to the evidences of design presented by the human body; nor was it necessary, for every physician knew them. The author dwelt upon that part of his subject at some length. Accepting gratefully all the facts of science, let us beware of rejecting everything that might not be capable of mathematical demonstration, and compelling our assent by absolute necessity. There might be truths more important, but less open; we might hear the deep but distant murmur of the immortal sea as it beat against the shores of Time, ready to bear upon its mighty bosom the children of men from life to life, and the law of continuity be found as true of the spiritual as it was of the material world.

The address was received with great applause.

On motion, ex-Presidents Davis, of Chicago, Gross, of Philadelphia, Toner, of Washington, and Richardson, of New Orleans, were invited to seats on the platform.

THE METRIC SYSTEM.

DR. E. SEGUN, of New York, made a report on the adoption of the metric system by the Association. On motion by Dr. Pallen, of New York, the consideration of the report was postponed until Thursday.

CONSOLIDATION OF SECTIONS.

DR. A. N. BELL, of New York, called up an amendment offered at the annual meeting in 1878, and moved its adoption. It provided for the consolidation of sections *four* and *five*, to be hereafter known as section *four*, on Medical Jurisprudence, State Medicine, and Public Hygiene, etc.

QUESTION AFFECTING REGISTRATION.

DR. LILLEV, of New Jersey, asked whether a gentleman who was not in affiliation with any regular medical organization, when such organizations existed in the State in which he resided, could register as a permanent member of the American Medical Association upon the claim that he *had been* in affiliation with such organization. Referred to the Judicial Council.

The Association then adjourned, to meet on Wednesday, May 7, at 9.30 A.M.

WEDNESDAY, MAY 7TH—SECOND DAY.

The Association was called to order at 9.30 A.M. by the President.

Dr. LOGAN, Chairman of the Committee of Arrangements, announced the following for election as

MEMBERS BY INVITATION.

Drs. T. H. Morgan, of Cochran, Ga.; A. Means, of Oxford, Ga.; J. R. Humphrey, of Acworth, Ga., and E. M. Nolan, of McDonough, Ga.

The following named gentlemen were elected permanent members: Drs. C. A. Simpson and John M. Johnson, of Atlanta, Ga.; Dr. George C. Dugas, of Ga.; J. A. Beasley, of Alabama, and M. J. Ealey, of Lafayette, Ga.

MATERIAL FOR DISSECTION.

A telegram was read from Dr. J. A. Morton, of Columbus, O., announcing that the bill making provision for material for anatomical dissection had passed the Legislature of that State.

On motion by DR. ATKINSON, of Philadelphia, the congratulations of the Association were extended to Dr. Morton, who had been mainly instrumental in securing the passage of the law.

PRESIDENT'S ADDRESS.

On motion of DR. A. C. POST, of New York, the Publication Committee was instructed to publish 5,000 copies of the President's annual address for *pro rata* distribution among the members of the Association.

DUTY ON QUININE.

DR. FRICKE, of Philadelphia, in accordance with instructions received from his County Medical Society, introduced a resolution asking that the American Medical Association request Congress to leave the present law regulating the duty upon quinine unchanged.

The resolution was laid upon the table.

DR. ROBERTS, of Nashville, introduced a resolution asking Congress to remove the duty upon the alkaloids of cinchona.

Carried.

ADDRESS OF THE CHAIRMAN OF THE SECTION ON PRACTICE OF MEDICINE, ETC., BY DR. THOMAS F. ROCHESTER, OF BUFFALO, N. Y.

YELLOW FEVER.

DR. ROCHESTER introduced his address by a reference to the epidemic of yellow fever which prevailed in the United States last year, and, with a view to answering the questions, Was it possible to ward off its invasion? or, in case of its appearance, to confine it within prescribed limits? he passed first to its *etiology*. Where the disease was born was known. It originated in the West Indies. It never originated *de novo* except in its primal birthplace. It could not be communicated from individual to individual by direct contagion, but through other media. The speaker then traced its mode of spread. Medicine would not cure it, nor would antiseptics or cleanliness prevent the progress of the disease. A *strictly enforced quarantine* was the means by which it must be arrested. Reference was then made to the successful quarantine at the port of New York. He believed that if any agent was ever found which would arrest the disease, it would be gasiform or aëriiform. He concluded that part of his address, by urging the establishing of a permanent National Health Bureau.

TYPHOID FEVER.

Reference was first made to the propagation of typhoid fever by means of *drinking-water*, and the credit given to Dr. Austin Flint, of New York, for first directing the attention of the profession to that

method about thirty-five years ago. Special reference was also made to a paper on typhoid fever, by Dr. Dr. Van de Warker, of Syracuse, and published in the *Popular Science Monthly*. Dr. Rochester then spoke of the propagation of the disease by means of ice, and cited several instances in which that mode of transmission was very apparent. He believed that the poison was not destroyed or impaired by freezing. A somewhat extended reference was then made to purification of sewage, and the opinion expressed that no sewer should be permitted to empty into a stream.

SANITARIA FOR THE TREATMENT OF PULMONARY PHTHISIS.

Under that head special attention was directed to Alpine sanatoria. Hygiene, in its largest sense, was recommended as the important factor in the management of the disease.

MATERIA MEDICA.

Instead of asking how little medicine was required, it was too common to act upon the principle of how much would be tolerated. Under that head attention was directed to certain new anesthetics, the too promiscuous use of jaborandi, etc. The new Dispensatory was commended.

PHYSIOLOGY.

Dr. Rochester, under that head, referred to papers by Flint and Busey, Flint, Jr., Richardson, of Boston; Longworth, Bowditch, Whittaker, Loring, and others. In conclusion, reference was made to the telephone and the phonograph. Their possibilities could not be fathomed. The address was referred to the Section on Practical Medicine.

ADDRESS OF THE CHAIRMAN OF THE SECTION ON STATE MEDICINE AND PUBLIC HYGIENE, BY DR. JOHN S. BILLINGS, OF WASHINGTON, D. C.

The number of patent ventilators and gas-traps was steadily upon the increase; but, in our knowledge of the causes of disease and the means of avoiding or destroying those causes, little or no positive advance had been made. So long as we had to contend with municipal and State authorities, which almost absolutely refused even the cost of obtaining reliable information, there was but little hope for satisfactory public hygiene.

If the law creating the National Board of Health was to succeed, it must be supported by medical men, and the call for aid from the Board should be responded to by the American Medical Association, which was the representative medical body of the nation. Its failure would, in a measure, be the failure of the medical profession, and its success would be their success.

The causes of want of interest in public hygiene by medical men were then noticed, and *First*, was the actual deficiency in accurate scientific knowledge upon the subject. There were but few physicians who would hesitate to act as health officers and give advice upon sanitary questions, and yet not one in one hundred had a thorough acquaintance with any one branch of public hygiene. Now, was it strange that such was the case, for the subject had for its true basis physics, biology, and political science.

Second. Another cause for the neglect of public hygiene was a distrust of the capacity and motive of some of those who were prominent as professed sanitarians, and that distrust was founded upon the necessary relations that existed between sanitarians and politicians. Such association, however, was inevitable.

The subject of *vital statistics* was then noticed, but

more especially the registration of deaths and disease. Such registration was a necessity to successful public hygiene. No scientific knowledge of the subject could be obtained until the character and the quantity of disease became a known quantity. Mortality statistics would not serve the purpose; and, until we learned how many cases of disease occurred under varying circumstances in different localities, no substantial advancement could be made. The difficulties of the registration of death statistics were then considered, and also the registration of disease. Special attention was directed to an opportunity to be offered for obtaining such statistics for the entire United States, as would be of positive value and furnish definite foundation for legislation with regard to public health. The opportunity would be afforded at the taking of the *next census*. He recommended that an appeal should be made to all the physicians in this nation, through the American Medical Association, to aid in furnishing the information needed. Books for the purpose would be sent to all physicians in the United States, as far as their addresses could be obtained, and they would be sent to any physician who made application for them.

An appeal was made to the medical press and to the profession to assist in the work.

The address was referred to the Section on Public Hygiene and State Medicine.

PRIZE ESSAYS.

DR. N. S. DAVIS, of Chicago, Chairman of the Special Committee to report on the recommendation made by Dr. Richardson in his annual address, relative to encouraging original investigation in medical science by means of prize essays, reported in favor of making alterations in the by-laws providing for four annual prizes of two hundred and fifty dollars each.

The report was signed by Drs. Davis, Gross, and Toner.

As an amendment to the by-laws, the report, under the rule, went over for one year.

CHANGES IN THE PLAN OF ORGANIZATION—PROPOSED AMENDMENTS.

DR. KELLER's amendment, that nominations for officers should be made only from the members and delegates present at any meeting, was laid upon the table by a vote of 120 to 5.

DR. CALDWELL's amendment, providing for a section on neurology and electrology, was laid upon the table without dissent.

DR. HITCHCOCK's amendment was tabled.

DR. MADDEX's amendment providing for a section on genito-urinary diseases gave rise to some discussion, and was referred to the Surgical Section for instruction by a vote of 78 to 73.

The following amendment, reported by Dr. N. S. DAVIS, of Chicago, namely: "And hence it is considered derogatory to the interests of the public and the honor of the profession for any physician or teacher to aid, in any way, the medical teaching or graduation of persons knowing them to be supporters and intended practitioners of some irregular or exclusive system of medicine," was opposed by Dr. E. S. DUNSTER, of Ann Arbor, Michigan, in a carefully prepared speech, was discussed by Dr. Davis, who suggested that, while he individually could not willingly teach students under such circumstances, the Association should be very careful about tying the hands of the profession in any respect, and bringing it into collision with public authority; and upon motion made by Dr. PRATT, of Michigan, was laid upon the table for one year.

COMMITTEE ON NOMINATIONS.

Drs. W. O. Baldwin, of Alabama; R. G. Jennings, of Arkansas; R. B. Cole, of California; C. Y. Chamberlain, of Connecticut; C. H. Richardson, of Delaware; J. M. Toner, of District Columbia; J. P. Wall, of Florida; G. G. Crawford, of Georgia; H. A. Johnson, of Illinois; J. F. Hibbard, of Indiana; H. B. Ransom, of Iowa; C. V. Motham, of Kansas; Dudley S. Reynolds, of Kentucky; E. S. Lewis, of Louisiana; T. L. Estabrook, of Maine; T. B. Evans, of Maryland; L. B. Warner, of Massachusetts; J. H. Jerome, of Michigan; J. H. Murphy, of Minnesota; E. P. Gale, of Mississippi; A. B. Sloan, of Missouri; S. Lilly, of New Jersey; E. Grisson, of North Carolina; M. A. Pallen, of New York; W. H. Mussey, of Ohio; S. D. Gross, of Pennsylvania; C. H. Fisher, of Rhode Island; F. P. Porcher, of South Carolina; J. D. Plunket, of Tennessee; H. W. Brown, of Texas; A. S. Payne, of Virginia; S. Marks, of Wisconsin; W. H. Forwood, of U. S. Army; and T. J. Turner, of U. S. Navy.

The Association then adjourned, to meet on Thursday, May 8th, at 9.30 A.M.

THURSDAY, MAY 8.—THIRD DAY.

The Association was called to order at 9.30 A.M. by the President.

PERMANENT MEMBERS.

The following gentlemen were elected permanent members: Drs. W. J. Harrell, of Bainbridge, Ga.; S. C. McCormick, of Duluth, Minn.; Thomas R. Wright and R. G. Eve, of Augusta, Ga.; W. W. Evans, of Oxford, Ga.; J. H. Low, James B. Baird, and J. T. Johnson, of Atlanta, Ga.; and A. G. Whitehead, of Waynesboro, Ga.

MEMBERS BY INVITATION.

The following gentlemen were elected members by invitation: Drs. Thomas J. Jones, of Hogansville, Ga.; J. P. Rosser, of Conyers, Ga.; C. F. Patillo, of West Point, Ga.; F. R. Calhoun, of Euharley, Ga.; R. H. Jenkins, of Hogansville, Ga.; David G. Hunt, of Dalton, Ga.; L. B. Alexander, of Forsyth, Ga.; C. H. Sayre, of New York; and J. B. Carlton, of Athens, Ga.

DUTY ON QUININE.

The Secretary read a communication that had been addressed to the Chairman of the Committee of Arrangements, and purporting to come from Powers & Weightman, of Philadelphia, and C. T. White, of New York, in which the statement was made that if the duty on quinine was removed they could no longer continue its manufacture.

The communication was laid upon the table.

RESOLUTIONS OF RESPECT.

Resolutions relative to the death of Wm. N. Compton were introduced by Drs. Grisson, Platt, and Toner, and adopted by the Association.

RESOLUTION RELATING TO THE CENSUS.

Resolved, That the American Medical Association earnestly recommends to each and every physician in the United States that he shall furnish such information as is requested by the Superintendent of the Census, and that he shall keep such record of his cases for the year beginning June 1, 1879, as will enable him to make this information accurate and reliable. Adopted.

REPORT OF COMMITTEE ON OZONE.

DR. DAVIS, of Chicago, Chairman of the Committee, reported, and offered the following resolution: *Re-*

solved. That a committee of *five* be appointed by the President, whose duty it shall be to investigate the practicability of carrying into active operation a plan for obtaining accurate meteorological and clinical observations, and report at the next meeting of the Association. Adopted.

THE REPORT ON NECROLOGY

was presented by Dr. J. M. Toner, and referred to the Committee on Publication.

THE REPORT ON SANITARIA FOR CONSUMPTIVES

was presented as received from Dr. H. I. Bowditch, of Boston, and, at his request, the Committee was continued, in order that it might be able to make the report complete. At the request of the Chairman, Dr. Wm. Pepper, of Philadelphia, was added to the Committee.

REPORT ON CATALOGUE OF NATIONAL LIBRARY.

The report announced that Congress had made an appropriation sufficient to allow of the early publication of two volumes.

REPORT OF COMMITTEE ON PUBLICATION.

Thirteen hundred copies of the Transactions for 1878 were published.

The report was referred to the Committee on Publication.

TREASURER'S REPORT.

The balance in the treasury at date was \$1,445.66. It was suggested that non-payment of dues for *two* instead of three years should work the forfeiture of permanent membership.

Report accepted and referred to the Committee on Publication.

REPORT OF LIBRARIAN.

The report showed that the library at present contained 2,816 volumes, exclusive of pamphlets.

Referred to Committee on Publication.

STATE MEDICAL SOCIETIES AND STATE MEDICINE.

Dr. S. E. CHAILLÉ, of Louisiana, read a paper upon the above subject before the Section on State Medicine and Public Hygiene. By the Section it was referred to the Association, and was read in general session. From general facts with regard to State medicine, and practical conclusions based upon the position occupied relative to the subject by thirty-seven State Medical Societies, he brought forward two important questions which had not been sufficiently considered by the Association—1. What was State medicine? and, 2. What could the Association do to the end that the practice of State medicine could be promoted? The progress of State medicine was dependent upon the enlightenment of public opinion. State medicine was the application by the State of medical knowledge for the common weal, and embraced every subject for the comprehension of which medical knowledge, and for the execution of which State authority, were indispensable. With reference to State medicine, physicians were prone to dwell upon, and to denounce an existing evil, whatever it might be, and to urge its correction, but did not tell *how* it was to be done.

In answering this second question, Dr. Chaillé presented the progressive steps made in Great Britain with considerable detail, for he believed they were the steps which must be taken in this country. To the end of giving the greatest benefit which could arise from the proper practice of State medicine, he proposed a *Standing Committee* upon the more efficient organization of the Association and *all* its branches. Perhaps an executive council should be constituted

and charged with the duty of devising ways and means to promote uniformity, as well as to strengthen and harmonize all of its practical operations. As at present constituted, the American Medical Association had little or no knowledge of its component parts; and a *head* which had no knowledge of its parts should be gotten rid of. He suggested that the Transactions of the Association be published after the manner of the Transactions of the British Medical Association. No physician residing in the United States should be elected either as a permanent member or as a member by invitation of the Association unless he was a member of the State Medical Society of his own State, if such an organization existed. Several propositions of like character, and affecting the re-organization of all County and State Medical Societies, were submitted, after which the paper was referred back to the Section on State Medicine for further consideration.

ADDRESS OF THE CHAIRMAN OF THE SECTION ON SURGERY AND ANATOMY, BY DR. MOSES GUNN, OF CHICAGO, ILL.

Dr. GUNN's address consisted of a careful and close argument upon

THE PATHOLOGY OF SUPPURATION.

He reviewed the theories which have been advanced regarding the origin of pus, by Virchow, Cohnheim, and Billroth, and the conclusion was reached that suppuration was not an unmixed evil. It was a dangerous thorn, from which occasionally, at least, a fragrant flower was plucked.

The address was referred to the Section on Surgery and Anatomy.

REPORT OF THE COMMITTEE ON NOMINATIONS.

Dr. S. D. GROSS, Chairman of the Committee on Nominations, announced that the committee was ready to make a report.

Dr. E. GRISSEM, Secretary, read the following, which was unanimously accepted:

For President—Lewis A. Sayre, M.D., of New York.

For Vice-Presidents: First—R. Beverly Cole, M.D., of California. *Second*—E. M. Hunt, M.D., of New Jersey. *Third*—H. O. Marcy, M.D., of Massachusetts. *Fourth*—F. Perye Porcher, M.D., of South Carolina.

For Treasurer—Richard J. Duglison, M.D., of Pennsylvania.

For Librarian—William Lee, M.D., of District of Columbia.

For Committee on Library—Johnson Eliot, M.D., of District of Columbia.

Next Place of Meeting—New York City.

Time of Meeting—The first Tuesday in June, 1880.

For Assistant Secretary—Walter R. Gillette, M.D., of New York.

For Committee of Arrangements—Dr. S. O. Vander Poel, of New York, Chairman; Drs. Stephen Smith, William M. Polk, Robert F. Weir, Charles Inslee Pardee, A. A. Smith, and Thos. T. Sabine, of New York; Dr. Joseph C. Hutchison, of Brooklyn; Dr. M. H. Burton, of Troy, N. Y.; and Dr. E. H. Parker, of Poughkeepsie.

For Committee on Prize Essays—Drs. Austin Flint, Sen., A. C. Post, J. W. S. Gouley, and M. A. Pullen, of New York City; and J. C. Hutchison, of Brooklyn, N. Y.

For Committee on Publication—Drs. W. B. Atkinson, T. M. Drysdale, A. Fricke, S. D. Gross, Casper Wistar, R. J. Duglison, of Pennsylvania; and Dr. William Lee, of District of Columbia.

The Committee also reported the following nominations for Chairmen and Secretaries of Sections for 1880:

I. *Practice of Medicine, Materia Medica, and Physiology*—Dr. J. S. Lynch, of Maryland, Chairman; and Dr. W. C. Glasgow, of Missouri, Secretary.

II. *Obstetrics and Diseases of Women and Children*—Dr. Albert H. Smith, of Pennsylvania, Chairman; and Dr. Robert Battey, of Georgia, Secretary.

III. *Surgery and Anatomy*—Dr. W. T. Briggs, of Tennessee, Chairman; and Dr. J. Powell Adams, of Minnesota, Secretary.

IV. *Medical Jurisprudence, Chemistry, and Psychology*—Dr. James F. Hibbard, of Indiana, Chairman; and Dr. Thomas F. Wood, of North Carolina, Secretary.

V. *State Medicine and Public Hygiene*—Alabama, Jerome Cleveland, M.D.; Arkansas, W. H. Hawkin, M.D.; California, W. F. Cheeny, M.D.; Colorado, C. Dennison, M.D.; Connecticut, C. A. Lindsley, M.D.; Delaware, Wm. Marshall, M.D.; District of Columbia, Thomas Antisell, M.D.; Florida, J. P. Wall, M.D.; Georgia, J. P. Logan, M.D.; Illinois, W. A. Johnson, M.D.; Indiana, J. F. Hibbard, M.D.; Iowa, J. A. Blanchard, M.D.; Kansas, D. W. Stomont, M.D.; Kentucky, S. Brundeis, M.D.; Louisiana, S. E. Chailié, M.D.; Maine, A. P. Snow, M.D.; Maryland, F. B. Evans, M.D.; Massachusetts, H. I. Bowditch, M.D.; Michigan, H. B. Baker, M.D.; Minnesota, C. N. Hewitt, M.D.; Mississippi, Wirt Johnson, M.D.; Missouri, H. H. Mudd, M.D.; Nebraska, J. Block, M.D.; New Hampshire, G. P. Conn, M.D.; New Jersey, D. A. English, M.D.; New York, A. N. Bell, M.D.; North Carolina, J. C. Walker, M.D.; Ohio, J. C. Reeve, M.D.; Oregon, H. Carpenter, M.D.; Pennsylvania, B. Lee, M.D.; Rhode Island, E. M. Snow, M.D.; South Carolina, R. A. Kenlock, M.D.; Tennessee, T. A. Aeberson, M.D.; Texas, H. W. Brown, M.D.; Virginia, F. D. Cunningham, M.D.; Vermont, L. C. Butler, M.D.; West Virginia, E. A. Hildreth, M.D.; Wisconsin, J. T. Reeve, M.D.; United States Army, Joseph R. Smith, M.D.; United States Navy, A. L. Gihon, M.D.

VI. *Ophthalmology, Otolology, and Laryngology*.—Dr. Bolling A. Pope, of Louisiana, Chairman; and Dr. Eugene Smith, of Michigan, Secretary.

For Judicial Council.—Drs. W. O. Baldwin, of Alabama; N. S. Davis, of Illinois; J. P. Gray, of New York; E. L. Howard, of Maryland; A. N. Talley, of South Carolina; D. W. Stomont, of Kansas; and J. P. Logan, of Georgia.

For Committee on Necrology.—Dr. J. M. Toner, of District of Columbia, Chairman; Drs. R. F. Michel, of Alabama; F. W. Hatch, of California; J. B. Cummings, of Arkansas; Chas. Dennison, Colorado; G. W. Russell, of Connecticut; J. H. Richards, of Delaware; J. P. Wall, of Florida; T. S. Hopkins, of Georgia; J. H. Hollister, of Illinois; G. L. Sutton, of Indiana; H. B. Ransom, of Iowa; C. V. Notham, of Kansas; D. S. Reynolds, of Kentucky; E. A. Lewis, of Louisiana; E. F. Sanger, of Maine; J. Morris, of Maryland; L. F. Warner, of Massachusetts; G. E. Ranney, of Michigan; D. W. Hand, of Minnesota; J. M. Richmond, of Missouri; J. R. Black, of Nebraska; L. G. Hill, of New Haven; H. D. Didama, of New York; J. Blain, of New Jersey; F. J. Hayward, Jr., of North Carolina; Starling Loving, of Ohio; Frank Woodbury, of Pennsylvania; C. H. Fisher, of Rhode Island; Manning Simons, of South Carolina; J. B. Lindsley, of Tennessee; H. W. Brown, of Texas; O. F. Fassett, of Vermont; L. S. Joynes, of Virginia; R. W. Hazlett, of West Virginia; J. T. Reeve, of Wis-

consin; J. J. Woodward, of District of Columbia, United States Army; and A. L. Gihon, of United States Navy.

ADDRESS OF THE CHAIRMAN OF THE SECTION ON OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN, BY DR. E. S. LEWIS, OF NEW ORLEANS, LA.

The address by Dr. Lewis consisted of a *resumé* of the literature during the past year upon abdominal palpation, puerperal fever, laparo-elytrotomy, change of posterior position, ligation of the cord, traction upon the lower jaw, treatment of post-partum hemorrhage, treatment of cancer of the cervix uteri, and the treatment of uterine fibroids.

The address was referred to the Section on Obstetrics, etc.

THE METRIC SYSTEM.

The Association took up the report made upon the metric system, by Dr. E. SEGUIN, of New York, and adopted the following resolutions:

Resolved, 1. That the American Medical Association adopts the international metric system, and will use it in its transactions.

2. Requests that those who present papers at its future meetings employ this system in their communications, or reprints thereof.

3. Requests the medical boards of the hospitals and dispensaries to adopt the metric system in prescribing and recording cases; and that the faculties of the medical and pharmaceutical schools adopt it in their didactic, clinical, or dispensing departments.

4. Requests the physicians familiar with the metric system to help their confrères and the druggists in its application; and the delegates present at this session to work up the acceptance of the metric system by their respective county and State societies.

5. Requests our president to name a metric executive committee, of which he shall be the ex-officio chairman, and whose task will be to give unity and rapidity to this metric movement.

DUTY ON IMPORTED BOOKS AND INSTRUMENTS.

DR. CHAILLÉ, of Louisiana, introduced a resolution petitioning Congress to pass a law removing the duty from any one book or instrument which should be imported to assist in the personal pursuit of scientific study. Adopted.

COPYRIGHT ON DRUGS.

DR. BRODIE, of Detroit, introduced a resolution which he asked to have referred to the Judicial Council: *Resolved*, That the use of articles thus protected by copyright is a distinct violation of the code of ethics. It was so referred.

DR. TURNPSEED, of South Carolina, offered an amendment providing for the formation of a section to examine and report regarding the merits and demerits of surgical and gynecological instruments presented at the meetings of the Association. Laid over under the rule.

The Association then adjourned to meet on Friday, May 9th, at 9.30 A.M.

FRIDAY, MAY 9TH—FOURTH DAY.

The Association was called to order at 9.30 A.M. by the President.

MEMBERS BY INVITATION.

The following gentlemen, on recommendation by the Committee of Arrangements, were elected members by invitation: Drs. J. J. Jones, R. N. Ross, and E. Cross, of Arkansas.

REPORT FROM THE SURGICAL SECTION.

The Surgical Section, through its Chairman and Secretary, reported that the proposition to establish a section upon genito-urinary diseases had been withdrawn.

RESOLUTIONS AFFECTING THE ORGANIZATION OF THE AMERICAN MEDICAL ASSOCIATION, OF STATE AND OF COUNTY MEDICAL SOCIETIES.

The following resolutions, based upon Dr. Chaillc's paper, were offered:

Resolved, That a committee on the more efficient organization of this Association and of its branches—consisting of *five* members, be appointed by the President.

Resolved, That this committee be instructed to devise and recommend ways and means to secure greater uniformity as well as greater strength of organization of the State medical societies, and all their auxiliary branches.

With these ways and means the following be considered.

1. The compilation of a model code of detailed regulations for the government of State and county medical societies.

2. The requirement from any State medical society of an annual report, to contain certain data (to be specified) necessary to show the condition and progress of each of these State societies and of their auxiliary branches; to also contain a brief summary of the peculiarities of this organization, and of the measures being used by it to promote medical organization; and still further, to contain a brief summary of the laws of the State in reference to State medicine, and of the efforts being made to promote the practice of State medicine. Such reports should be published in the transactions of each State medical society.

3. The publication, in annual transactions of this Association, of a consolidated report of the above reports from each State, together with special notice of the meritorious work done by any of the branches of this Association.

4. The substitution of a periodical medical journal for the present volume of transactions.

5. The non-recognition by this Association of State medical societies which make no provisions encouraging the organization of auxiliary societies in counties, etc.

6. The advisability of electing no person, either as permanent member or member by invitation, unless such person be a member of a State medical society, provided that there be such a society, and recognized by this Association, in his State.

7. The advisability of refusing to admit to this Association delegates of the societies auxiliary to the State societies, unless the certificates of delegation be endorsed by the authorized officer of the State Society.

8. The advisability of refusing to admit any delegates except those selected from and elected only by voting members who have paid all fees due to their respective county and State societies, and of establishing the principle that only those members of branch societies who are entitled to vote, and have paid all fees due, shall be entitled to delegates.

9. The advisability of urging every medical college to have not less than one lecture delivered to every graduating class on the importance to the profession and to the people of medical organization.

The President appointed as committee to report upon the above resolutions: Drs. Foster Pratt of Michigan; S. D. Gross, of Pennsylvania; N. S. Davis,

of Illinois; A. N. Bell, of New York, and Alonzo Garcelon, of Maine.

A communication relating to

INTERVENTION OF PHYSICIANS IN EDUCATION

was received from Dr. R. J. O'Sullivan, of New York, and the request that the committee be continued was granted.

DELEGATES TO FOREIGN MEDICAL SOCIETIES.

Dr. E. Seguin, of New York; Dr. L. T. Yandell, of Kentucky; Dr. J. M. Da Costa, of Pennsylvania; Dr. Moses Gunn, of Illinois; and Dr. L. Turnbull and Dr. E. Warner, of Paris, were elected as delegates to represent the Association in medical societies in Europe; and Drs. J. C. Hutchinson, of New York, and Wm. Brodie, of Michigan, as delegates to the medical societies in Canada.

RESOLUTIONS REGARDING THE PUBLICATION OF THE VOLUME OF TRANSACTIONS.

The Committee on Nominations reported the following resolution: *Resolved*, That the Committee on Publication be instructed to advertise for proposals to publish the transactions of this Association in *six* of the largest cities of the Union, and that the contract be awarded to the lowest and most responsible bidder.

Dr. A. M. Pollock, of Pennsylvania, moved to lay the resolution on the table. Motion was lost.

Dr. Foster Pratt, of Michigan, moved to amend by striking out the words "in six of the largest cities of the Union." The amendment was lost by a rising vote of ayes 21, nays 27. The original resolution was then adopted.

HONORARIUM FOR THE SECRETARY.

On motion made by Dr. Grissom, of North Carolina, an honorarium of six hundred dollars [\$600] was voted for the Permanent Secretary.

COMMITTEE ON OZONE.

The following Committee on Ozone was appointed by the President: Drs. N. S. Davis, of Ill.; J. M. Toner, of D. C.; S. M. Bemiss, of La.; W. H. Geddings, of S. C.; and H. O. Marey, of Mass.

METRIC EXECUTIVE COMMITTEE.

The following Metric Executive Committee was announced: Dr. Theophilus Parvin, of Ind., Ex-officio Chairman; Dr. E. Seguin, of N. Y.; Dr. E. Wigglesworth, of Mass.; Dr. J. R. Weist, of Ind.; Dr. E. R. Squibb, of N. Y.; and Dr. Wm. B. Atkinson, of Pa.

ADDRESS OF THE CHAIRMAN OF THE SECTION ON OPHTHALMOLOGY, OTOTOLOGY, AND LARYNGOLOGY, BY DR. H. KNAPP, OF NEW YORK.

Dr. Knapp's address consisted of brief references to a number of subjects, and a notice of some of the more important advancements made in the departments of ophthalmology and otology.

Iridectomy in chronic glaucoma was giving way to *sclerotomy*. *Sympathetic ophthalmia* was transmitted by the ciliary instead of the optic nerve, as advocated by some. Reference was made to *cataract extraction*, to the use of *eserine* and *duboisine*, to ophthalmoscopes, to lid-holders, to tumors of the eye, and to works on pathological anatomy.

Otology showed less extensive, but no less marked advancement than ophthalmology; and reference was made to discoveries in acoustics and the management of mastoid inflammation. A number of instruments and pathological specimens were exhibited.

The address was referred to the Committee on Publication.

PRIZE ESSAYS.

The Committee on Prize Essays submitted the following report: That the prize of one hundred dollars (\$100) be awarded to Dr. ALLAN McLANE HAMILTON, of New York City, for an essay on certain forms of primary and secondary (local) degeneration of the lateral columns of the spinal cord, with special reference to an infantile rare form.

RESOLUTIONS OF THANKS.

DR. N. S. DAVIS, of Chicago offered resolutions of thanks to the President of the Association, to the Governor of the State of Georgia, to the Mayor of the city of Atlanta and to all her citizens, to the various railroad and steamship companies that had extended favors, to the local press, and to the Committee of Arrangements, expressing the hearty gratitude of the American Medical Association for the uniform kindness, hospitality, and courtesy which its members had received.

The resolutions were unanimously adopted by a rising vote.

The report of the delegates to the Canada Medical Association was presented by Dr. Wm. Brodie, of Detroit, Mich., and entered upon the minutes.

REPORT OF JUDICIAL COUNCIL.

The Judicial Council reported in reference to Allen County matters, Indiana, that it be postponed until the next annual meeting; and that the American Medical Association did not regard the delegates from the Arkansas Medical Association as entitled to registration, because it did not regard the Society which they represented as a State medical society.

The report was accepted and entered upon the minutes.

REPORT OF COMMITTEE ON STATE BOARDS OF HEALTH.

The Committee on State Boards of Health, who are required to report annually the results of their efforts, state that they addressed the usual memorial to the executives of the States still without State boards of health, and were assured by some of the executives that they would use their efforts to the end desired. They are happy to announce that the legislature of the State of Delaware has adopted such an act, and the board of health of that State is now in process of organization. We now have nineteen State Boards of Health: Alabama, California, Colorado, Connecticut, Delaware, Illinois, Kentucky, Louisiana, Missouri, Michigan, Minnesota, Mississippi, New Jersey, North Carolina, Rhode Island, Tennessee, Texas, Virginia, and Wisconsin. [Signed] W. B. ATKINSON.

The last business in order was the instalment of new officers.

DR. PARVIN, in appropriate remarks, thanked the Association for the honor conferred upon him, the uniform courtesy which it had extended to him during the deliberations of the present meeting, and in laudatory words introduced the President-elect, Dr. Lewis A. Sayre, of New York, who expressed his feeling of appreciation for the highest honor that could be bestowed upon a medical man in this country.

On motion, the President declared the Association adjourned, to meet in the city of New York, on the first Tuesday in June, 1880.

A PHILANTHROPIC BEQUEST.—M. Möring, director of the Department of Charities in France, has just received from a generous benefactor, who chooses to remain unknown, the sum of 300,000 fr. (\$60,000), to be expended in the establishment of a home for superannuated workers in metals.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, May 1, 1879.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

AFTER the reading and approving of the minutes, Dr. E. H. Janes, from the Committee on Admissions, reported favorably on the names of the following candidates for resident fellowship, who were afterward duly elected: E. Sanders, Glover C. Arnold, John J. Milhau, Clement Cleveland, William H. Welch, John Shrady, and P. F. Chambers.

There were present, as guests, Dr. David King, of Newport, and Dr. J. W. Roseburgh, of Hamilton, Canada; and these gentlemen were invited by the President to take seats beside him.

The Librarian, Dr. Laurence Johnson, announced that since his last report there had been received thirty-eight bound volumes, seventeen unbound volumes, and eight hundred and seventy-seven pamphlets and journals, and mentioned a number of the names of the donors.

The Corresponding Secretary, Dr. John G. Adams, then made a brief report, and also presented to the Academy a framed copy of the programme of the old Broome Street School of Medicine, which was organized in 1836. It was started by six physicians and surgeons, of whom Dr. Post and himself were now the only survivors, and he believed that in it the first course of spring and autumn lectures ever given in New York was delivered. It was also, as far as he knew, the first private medical school ever gotten up in this city.

After a report by the Committee of Ways and Means, through its chairman, Dr. James Anderson, the paper of the evening was read by Frank H. Hamilton, M.D., LL.D., on

POSTURE AS A MEANS OF RELIEF IN STRANGULATED AND INCARCERATED HERNIA, WITH A GENERAL CONSIDERATION OF THE MECHANISM OF REDUCTION.

In a late number of the *British Medical Journal* there had been published an interesting account of a case of intussusception in a child, which was cured by means of copious injections of thin gruel into the bowel. Dr. Blaker, the physician in whose practice it occurred, attributed the good result obtained mainly to the three following points:

1. Complete anæsthesia, induced by chloroform.
2. An early resort to the injection of gruel.
3. The position of the child when the injections were made, viz.: lying on its back, with the nates raised upon a pillow.

Dr. Hamilton was inclined to attribute more benefit to the last agency than the gentleman reporting the case seemed to do, and the main object which he had in writing the present paper was to set forth his views in regard to the importance of posture in the reduction of strangulated hernia, as well as the reasons why certain positions of the body were of service. When he first contemplated it, he intended it to include a consideration of spasmodic colic and ileus also; but, on account of the extensiveness of the subject of hernia, he was obliged to postpone those topics until some other occasion.

He had collected fourteen cases of strangulated hernia occurring in his own practice, in which a reduction had been accomplished mainly through the agency of posture, but for lack of time he would be able to recite only two or three of them as specimens. Case Number Three of these was as follows: In 1865,

while on duty as one of the attending surgeons to Charity Hospital, his attention was called by the house-surgeon to a male convict suffering from an indirect inguinal hernia which had become strangulated. When he first saw him ineffectual efforts at reduction had been kept up during the whole of the preceding night, and the man was now very anxious to take an emetic, as he said that once before, when his hernia had become strangulated, this had relieved him. It was deemed unadvisable to administer an emetic; but while the house-surgeon was making the preparations for an operation, which it was feared would have to be resorted to, Dr. Hamilton concluded to try the effect of placing the man on a steep inclined plane, with the head downward. Accordingly, the foot of the bed was elevated until its legs rested upon a table; when, in about ten minutes, he had the satisfaction of seeing the hernial tumor disappear altogether. Another case was related very similar to this, which had occurred previously in Buffalo. In 1871, Dr. Hamilton was called to see, in consultation, a gentleman who three days before had been seized with a severe pain in the region of the gall-bladder, which was at first naturally supposed to be due to the passage of a gall-stone. Somewhat more than twenty-four hours before he was called in, however, it was discovered that a hernia (although he had never before had anything of the kind) had descended into the scrotum, and was now strangulated.

He directed that the feet of the patient should be lifted on the shoulders of a strong man; but, after this position had been tried for some time, the strangulation still continued as before. Complete anesthesia by means of ether was now secured, and then the experiment of elevating the feet in the same manner was again tried; when immediately there followed a successful reduction.

Besides the fourteen cases mentioned above, Dr. Hamilton had seen quite a large number of others in which reduction had been secured by means of posture, but of these he had preserved no special record. Then, in former papers published by him in the *Belleue* and *Charity Hospital* reports, notes had been given of twenty-three cases in which other methods in addition to that of posture had been employed; but even in these he regarded this as the chief agency of successful reduction.

THE CAUSES OF STRANGULATION.

In order that the mechanism of reduction might be properly appreciated it was necessary that we should arrive at some definite conclusions as to the true causes of strangulation. It had long been taught by various authorities that

MUSCULAR SPASM

was a most important element in its causation, and in support of this view the writer quoted a passage from *Velpeau*, which concluded as follows: "All muscular contraction *must* increase the strangulation." Sir *Astley Cooper*, in speaking of strangulation at the upper ring, stated that a portion of the intestine protruded under the transversalis and internal oblique muscles, and was compressed by them. *Ferguson* spoke of the use of anti-spasmodics in reduction, and many other authors might have been quoted to the same effect, if time had permitted.

Dewitt said that muscular spasm was *formerly* considered to be a cause of strangulated hernia; but the writer feared that many surgeons still retained this old idea. Dr. *Hamilton* believed that *Velpeau* and Sir *Astley Cooper* were entirely wrong in their opinions on this subject, and he remarked that whatever an-

atomical reason might be cited in favor of their view, there remained a sufficient pathological reason why this was erroneous, viz., that muscular spasm was always too intermittent and brief in duration to constitute the cause of a condition like strangulated hernia. Such a view of the causation could not therefore be accepted, notwithstanding the high authorities that could be quoted in its support. *Skey* not only positively denied the agency of muscular spasm, but stated that this was now altogether an antiquated and exploded notion. Antiquated it undoubtedly was; but he regretted that it was hardly as yet to be considered as exploded, since so many still seemed to adhere to it, in spite of the arguments that were adduced to disprove it.

The next point to investigate was, what was

THE EFFECT OF NORMAL MUSCULAR TENSION.

As a general rule, the position of the patient had no effect upon hernial apertures. Flexing and rotating the thigh inward was frequently recommended in order to facilitate the return of a hernia; but it could be easily shown that such manoeuvres were in no way instrumental in relaxing the internal ring, at which the strangulation exists in the vast majority of instances. In hernias of long standing the canal usually acquired an almost cartilaginous hardness, and it was not, therefore, capable of being either enlarged or diminished by posture. Consequently, the diameter of the ring was not affected; and besides, in a considerable proportion of cases the strangulation occurred in the sac itself in these old hernias. The conclusion that must be arrived at, then, was that there were but very few cases in which either muscular spasm or normal muscular action were capable of influencing hernial apertures. In

FEMORAL HERNIA

the internal or crural ring was almost always the seat of stricture, and it had long ago been demonstrated that posture had no effect in giving relief here. *Velpeau* and other authorities had acknowledged this; and one reason was the important anatomical position that *Gimbernat's* ligament held in reference to this condition.

We had now to consider whether in

DIAPHRAGMATIC AND VENTRAL HERNIAS

(where there were no natural openings), muscular spasm might not be directly concerned in the causation. In consequence of its position, diaphragmatic hernia was entirely removed from observation; but the writer had had the opportunity of seeing a large number of cases of ventral hernia produced by stabs and other similar wounds, as well as some due to gunshot injuries, which one would naturally suppose to be a more frequent cause of this than is actually the case. All such strangulated hernias were difficult to reduce, until the patient had been brought under the influence of an anæsthetic. But in no case had simple relaxation of the muscles proved sufficient; and this was not difficult to explain. In all strangulated hernias the hernial opening was stretched to the utmost. If it were not, there would of course be no strangulation. Consequently, instead of a simple slit, there was now a circular aperture. If we were to suppose, for example, that there was a body like the finger, or a piece of omentum blocking up such an opening, it would be silly to imagine that any amount of muscular relaxation would release it. The same was true in regard to the intestine, which, as a general rule, practically represented a solid mass.

By what other means, whether local or general,

could we hope to relax these apertures? The old surgeons were accustomed to resort to such local measures as the application of warm fomentations, liniments, belladonna ointment, etc. Even at the present day there were good surgeons who recommended warm fomentations, and Prof. Gross advocated cold fomentations; but he believed it would be a difficult task for such authorities to show how fomentations, whether warm or cold, could have the effect of relaxing such openings. There was much more speciousness in the idea that this result could be accomplished by the employment of such general agents as chloroform and other anaesthetics, blood-letting, tobacco-enemata, etc.

That such means were instrumental in relaxing the apertures had seemed a necessary inference; but Dr. Hamilton was not willing to accept this conclusion, since he did not believe that it was founded on sound anatomical and pathological premises. On the other hand, there were more satisfactory explanations of which we might avail ourselves; and it was important to bear in mind in this connection that it was the muscular fibres alone (and not the tendons of muscles), which were relaxed by such agents.

What, then, was

THE TRUE THEORY OF REDUCTION

in the great majority of instances? It had been sufficiently demonstrated, he thought, that it did not ordinarily consist in the relaxation of the hernial canal or rings; and he would now endeavor to show that the reduction was in reality effected by the employment of external pressure, in the form of taxis, and by internal traction: the operation of these forces always being greatly facilitated by paralysis of the muscles. Of the value of taxis, tested as it had been by such long and universal experience, there could be no doubt; but of the practical efficiency of internal traction, less was understood by the profession. This kind of traction might be caused in a variety of ways. Thus, emetics might produce it by the sudden upheaval of the abdominal viscera toward the upper portion of the cavity which they occasioned; and the same was true of cold water dashed suddenly upon the bare skin. In both cases, however, there was also a contraction of the muscles. Emetics, in addition, had sometimes the effect of inducing a violent anti-peristalsis in the intestines. Cathartics were probably of service only by exciting peristaltic or anti-peristaltic movements, and Skey had stated that they caused a dragging-up of the bowel from the sac. But in actual practice neither emetics nor cathartics were often now employed; because, if they were not successful in causing a reduction, they were apt to do harm by increasing the tendency to inflammatory action. In order to facilitate whatever means were made use of, it was generally recommended that the bladder should be emptied, and that, if there was any accumulation of gas in the lower part of the bowels, it should be removed. For the latter purpose, as well as the removal of fecal matter, enemata were serviceable, and, besides, sometimes had the effect of exciting violent peristaltic efforts. Tobacco-enemata had long been held in repute in strangulated hernia, and were of great service in relaxing the abdominal muscles; but Dr. Hamilton could not believe that this or any other agent (except perhaps in very rare instances) was capable of causing an enlargement of the hernial openings. Still, even when tobacco was employed, he thought that the peristalsis set up by it was its most efficient result, and that the muscular relaxation resulting

from its use was of secondary importance to this. It was an agent not without danger, however, and death had been known to follow from the prostration which it caused. Chloroform, bleeding, and warm baths, all had the effect of relaxing the muscles which resisted the return of the hernia (not of relaxing the apertures), and of these chloroform was the most efficient. Of how much service such an effect was, we could better appreciate if we considered the subject of abdominal wounds for a moment. In knife-stabs and other short wounds in the abdomen, it was almost impossible to prevent extrusion of the viscera; while in large incisions, such as were made in ovariectomy, for instance, there was no tendency of this kind, because the great muscles were thereby completely relaxed. In the same manner the muscles were paralyzed by such agents as those mentioned above, and, consequently, their resistance to taxis overcome. The effect of opium was probably much the same, although its action was somewhat more difficult to explain.

DR. HAMILTON at this point wished to make the suggestion that while the patient was under the influence of such remedies, and the abdominal muscles thus relaxed by them, the hernia might actually be withdrawn by violent peristalsis or anti-peristalsis in the intestine. It was well known that peristaltic movements often continued for some time after death, and he himself had seen this demonstrated in several instances in the case of calves. Niemeyer and other observers had noticed a number of invaginations of the intestines at the autopsies of children who had died of hydrocephalus, which had been produced by the violence of *post-mortem* peristaltic movements. Might it not be true that in the [same way these peristaltic movements went on under the temporary paralysis produced by chloroform, bleeding, etc., just as in labor uterine contractions continued, and were sometimes increased when the patient was under the influence of an anaesthetic? It seemed reasonable to suppose, therefore, that one way, at least, in which the above agents acted was by putting the abdominal muscles in such a condition that their contractions could not interfere with the continuance or increase of peristalsis.

(To be continued.)

Obituaries.

CHARLES MURCHISON, M.D., LL.D., F.R.S., OF LONDON, ENGLAND.

DR. MURCHISON died very suddenly from disease of the aortic valves, on the 23d of April last. In him medicine has to lament a man who not only ornamented the profession by a noble and upright character, but who with untiring and conscientious industry, was always adding to medical knowledge.

Dr. Murchison graduated in medicine at Edinburgh in 1851, having, while a student, won many prizes and medals. His career since then has been so eventful with honors to himself, and noteworthy to the profession, from his contributions to its literature, that we can hardly chronicle everything. He finished his education in Italy and Paris, and then returned to Edinburgh for a time. In 1853 he went to India, and was soon appointed Professor of Chemistry in the Bengal Medical College. Returning to England he

became, in 1855, Fellow of the College of Physicians, and later, Demonstrator of Anatomy and Lecturer on Botany at St. Mary's Hospital. During these years he wrote considerably on botanical subjects. In 1856 he began his pathological studies, and although a man who was always careful and exact in his writings, he had soon contributed no less than 311 papers to the London Pathological Society. These were based largely on the pathological collections at St. Mary's, and they added greatly to the prestige of the society and the hospital, as well as to his own reputation.

In 1856 he was appointed assistant physician to King's College Hospital, and also to the London Fever Hospital, his connection with the latter institution resulting in his crowning work on Continued Fevers. In 1860 he became lecturer on pathology at the Middlesex Hospital, and assistant physician at the same place. He was made physician to the London Fever Hospital in 1861.

Resigning this he became physician and sole Lecturer on Medicine at Middlesex Hospital, in 1866. In 1870 he received the degree of M.D. from Edinburgh University. In 1871 he became Lecturer on Medicine at St. Thomas's Hospital. In 1873 he was appointed Croonian Lecturer of the Royal College of Physicians, in which capacity he delivered his lectures on functional derangements of the liver. He subsequently became President of the Pathological Society, and one of his latest honors was his appointment as physician in ordinary to the Duke and Duchess of Connaught.

During all these years his literary activity was extraordinary. Besides translating Ferrieh's "Diseases of the Liver," and other foreign works, he was a frequent contributor to medical journals and the transactions of societies. In 1862 he published his great work on *The Continued Fevers of Great Britain*. In this he first made the unalterable distinctions between typhus and typhoid, and drew the aetiology and symptoms of the continued fevers with such exhaustive clearness, as made him at once the authority above all others on the subject.

We have had space to do little but catalogue a partial list of his achievements and give some indication of the amount of his work. But even this will show the talents and tremendous industry of the man.

For the last nine years of his life he had been aware of a disease of the heart, but had continued his work, and died in the midst of it while attending to a patient.

THOMAS J. CORSON, M.D.

THOMAS J. CORSON, M.D., died at Trenton, N. J., May 10th, after a long and painful illness, in the fifty-first year of his age. He was a prominent citizen and widely known throughout the State of New Jersey. During his career he held several high positions of trust and honor. He was a member of long standing in the Masonic order, having attained to the thirty-third degree, was High Priest of the Royal Arch Masons and Grand Commander of the Grand Commandery of Knights Templar. At one time he was president of the State Medical Society. It was at his instigation, in the winter of 1878, that the investigation into the management of the State Prison was gone into, he having preferred charges against the attendants for cruelty to the convicts, which at the time created such widespread interest. He was a quiet, unassuming man, and was noted for his sound medical common sense.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from May 4 to May 10, 1879.

SUTHERLAND, C., Colonel and Surgeon. Granted leave of absence for five months on Surgeon's certificate of disability. S. O. 105, A. G. O., May 3, 1879.

STORROW, S. A., Major and Surgeon. Granted leave of absence for one month. S. O. 38, Dept. of the Platte, May 5, 1879.

BARTHOLOMEW, J. H., Capt. and Asst. Surgeon. Relieved from duty at Alcatraz Island, and assigned to temporary duty as Post Surgeon at San Diego Barracks, Cal. S. O. 44, Div. of the Pacific and Dept. of California, April 28, 1879.

WINNE, C. K., 1st Lieut. and Asst. Surgeon. Relieved from duty at Fort McPherson, and assigned to duty at Fort Washakie, Wyo. T. S. O. 35, C. S., Dept. of the Platte.

WORTHINGTON, J. C., 1st Lieut. and Asst. Surgeon. To report by letter to the Medical Director for special duty. S. O. 50, Dept. of Arizona, April 23, 1879.

BIART, V., 1st Lieut. and Asst. Surgeon. Granted leave of absence for thirty days, with permission to apply for an extension of thirty days, on Surgeon's certificate of disability. S. O. 88, Dept. of the Missouri, May 5, 1879.

RANDOLPH, J. F., Major and Surgeon. Having been found by an Army Retiring Board incapacitated for active service, he is granted leave of absence until further orders, on account of disability, to take effect May 1, 1879. S. O., 108, A. G. O., May 7, 1879.

CHICAGO MEDICAL SOCIETY. — At the annual meeting of the Chicago Medical Society, held April 7th, Dr. Edmund Andrews was elected President, and Dr. R. G. Bogue, Vice-President.

A resolution was adopted authorizing the appointment of a committee to memorialize the Mayor-elect, Hon. C. H. Harrison, to place the Department of Health of this city beyond the pale of politics, as is the case now with the Police and Fire Departments, and to retain in his position of Commissioner, Dr. De Wolfe, in the interest of sanitary science and good government. In the vote on the resolution there was not a dissenting voice. Dr. De Wolfe was appointed under a republican administration, while the incoming Mayor is a democrat.

THE AUSTRIAN UNIVERSITIES. — The Austrian government has published a comparative statement of the condition of the universities of the Empire at the periods of the two Paris Expositions, 1867 and 1878.

In 1867 there were in Austria six universities, four complete, viz., Vienna, Prague, Gratz, and Cracovia; and two incomplete, *i. e.*, without a Faculty of Medicine, viz., Innsbruck and Lemberg. At present there are seven universities, five of which are complete, Innsbruck having received a Medical Faculty in 1869. When the government decided to found a new university, all the nationalities of the Empire sought eagerly for the favor, but Czernovitz was finally chosen as its site. The decree for its establishment is dated September 30, 1875. During the present century, two Austrian universities, that counted their age by centuries, have been abolished, viz., that of Salzburg, which was closed in 1810, after having existed for two centuries, and that of Olmutz, suppressed in 1855, after having seen three centenaries.

The budget of the universities in 1867 was 1,242,088 florins (\$621,044). If we take the University of Vienna as an example of the changes brought about in ten years, we find that in 1867 there were 66 regular professors, 31 assistant professors, and 72 tutors (*privat docentes*), while at the present time the numbers are respectively 88, 44, and 91.

SIMPLE TREATMENT FOR SCIATICA.—Dr. Ebrard, of Nîmes, states that he has for many years treated all his cases of sciatica and neuralgic pains with an improvised electric apparatus, consisting merely of a flat iron and vinegar, two things that will be found in every house. The iron is heated until it is sufficiently hot to vaporize the vinegar, and is then covered with some woollen fabric, which is moistened with vinegar, and the apparatus is applied at once to the painful spot. The application may be repeated two or three times a day. As a rule, the pain disappears in 24 hours, and recovery ensues at once. The rationale of the process is plain: the iron is magnetized by the heat, and, if the acid be then added to it, electricity is produced, and the same effects are obtained as with an electric battery.—*Jour. de Méd., etc., de Bruxelles.*

EXAMINATION FOR F.R.C.S.E.—The questions below were put to candidates for their primary examination for Fellowship at the Royal College of Surgeons of England, November 15th:

1. Describe the dissection required to expose the upper surface of the first rib, and mention in order, from before backward, the several structures in immediate relation with that bone.

2. A transverse section is made through the cranium and its contents, passing through the odontoid process. Mention in order, from above downward, the several structures which would be divided.

3. Describe the development of the vertebral column and mention the form of the vertebral centrum characteristic of each of the primary divisions of the vertebrata.

4. Describe the structure of the supra-renal capsule, and give the evidence which at present exists regarding its function.

PYRIFORM SWELLING OF THE LARYNX IN TUBERCULOSIS.—At a recent meeting of the Philadelphia Academy of Natural Sciences, Dr. Seiler said he had been interested in the anatomy of the larynx, and had recently ascertained that very peculiar symptoms were manifested by this organ in the very earliest stages of consumption. An opportunity to investigate this subject was recently offered in the case of an infant which had died of acute tuberculosis. In this case, of which he had made sections of the organ, which he exhibited, the arytenoid cartilages were found to be swollen at one extremity, so as to assume a pear shape. This "pyriform swelling" of these cartilages

appeared so early in the course of the disease that by means of it a very early diagnosis might be made and thus much be done to arrest if not cure the trouble.

LEPROSY IN SPAIN.—A letter from Madrid informs us that leprosy has made its appearance in several localities in the province of Alicante, and that the authorities, alarmed by the number of cases and of deaths, intend to establish a special lazaret. It is very generally believed that this horrible disease is only met with at the present time in Asia and Africa, but unfortunately this is a mistake. It still exercises its ravages in Europe, especially in Spain, where it has attained dimensions that furnish serious cause for alarm. In the province of Valencia, 116 cases of leprosy, 71 of which proved fatal, were reported last year. Of the 45 survivors, 17 are women. Even the above number, however, is probably below the truth, as the majority of the affected persons use every effort to hide their malady from the official inquirers and even from their nearest relatives. At Saint-Simat de Valldigna, the inhabitants call leprosy the "mal de Maure," and at Enguerra it is called the "mal de Saint-Lazare." In the provinces of Valencia and Alicante, it manifests itself under two forms: the tubercular, or leprosy of the Greeks, and the vulgar (anæsthetic), or leprosy of the Jews. Cases of recovery are extremely rare. Near Valencia, there has existed for a long time a hospital set apart exclusively for lepers; all who refuse to enter the hospital are isolated and subjected to the most rigorous hygienic rules.

HOMŒOPATHIC RESOLUTIONS.—The Homœopathic Medical Society of the State of New York, at its last annual meeting, adopted the following as supplementary to their resolutions of last year:—"That we clearly and emphatically distinguish between a 'therapeutic law' and the laws of chemistry, physics, and hygiene; and while in the treatment of disease the formula, '*causa sublata tollitur effectus*,' is often to be remembered and used with advantage, yet such laws and such action in no way infringe upon or invalidate the therapeutic law, '*similia similibus curantur*.'"

That we have not in the past, nor do we now, yield one tittle of our rights as physicians to use any means or appliances of the general profession to aid in the treatment of our patients (under the homœopathic law), or in the palliation of their suffering through the application of any physical, surgical, chemical or hygienic law, leaving the question of such use to the individual judgment of the practitioner, assured that they will be the least used by those who are the best acquainted with our *materia medica*, and best able to wield its immense *armamentarium*.

"In relation to the dose of the *similimum* proper to be exhibited, we discover that the most brilliant triumphs of homœopathy have been achieved by the use of attenuated medicines; yet, as a matter of fact, we find that even the crude drug in minute doses will exhibit power to become a remedy under our therapeutic law.

"But, as we as yet have not been able to deduce a law to guide us in determining the amount of a drug to be used, or the attenuation to be exhibited in order to meet the demands of any case most accurately, this society, while on the one hand it refuses to join with those who decry attenuated medicines, on the other will not refuse to recognize as brethren those who, governed by their honest convictions, can only exhibit crude medicines or the lowest attenuation in the treatment of the sick."—*Evening Post.*

Original Lectures.

SCLEROSIS OF THE POSTERIOR AND THE LATERAL COLUMNS OF THE SPINAL CORD.

A CLINICAL LECTURE DELIVERED AT CHARITY HOSPITAL.

By A. McLANE HAMILTON, M.D.,

VISITING PHYSICIAN TO THE HOSPITAL FOR EPILEPTICS AND PARALYTICS.

(Reported for THE MEDICAL RECORD.)

LECTURE I.

GENTLEMEN:—I propose to-day to present a number of patients in the cases of whom are illustrated two very interesting diseases: 1st, that commonly known as locomotor ataxia; and, 2d, primary sclerosis of the lateral columns of the spinal cord, or spasmodic spinal paralysis.

I will first present three patients who illustrate most perfectly the three stages of locomotor ataxia.

CASE I.—This man, *æt.* 57, and married, has suffered from the disease for two years. Before the appearance of any symptoms he had for a long time indulged freely in venereal pleasures, and was the subject of repeated priapism and nocturnal emissions, the erections occurring, as a rule, without any special erotic thoughts or stimuli.

He first complained of shooting pains in the back and limbs, numbness of the lower extremities, and a feeling of constriction about the waist and ankles, but no headache. Shortly after he noticed that he had difficulty in walking, and found that he had but poor control over his feet, and it soon became difficult for him to walk in the dark; and this difficulty in walking has steadily increased.

Six months ago the movements of the upper extremities first began to be ataxic.

The patient, as you see, is *anæmic*, badly nourished, and presents a *cachectic* appearance. He rises from his chair unassisted, but cannot stand with his eyes closed. His gait is ataxic, but there is no paralysis whatever, nor atrophy, and when I endeavor to hold his foot, his leg and thigh being flexed, while he tries to extend them, you will see I have great difficulty in doing so. There is marked *anæsthesia*. The *anæsthesia* is of the tactile variety, for he has no difficulty whatever in perceiving changes in temperature, but cannot tell anything about the location of the point of the *æsthesiometer*, or the nature of an object which is brought in contact with his skin when his eyes are closed. He has slight constipation and urinary trouble. There are also shooting pains in the extremities, with marked loss of co-ordination.

As he sits with his legs crossed, I will give him a sharp blow upon the *ligamentum patellæ*, and it is found that there is a sudden extension of the corresponding leg. This phenomenon can be observed in both legs. It has been said by Westphal and Erb that the absence of this phenomenon is pathognomonic of the early stage of the disease, but the records of several recent observers have led us to regard it as a symptom which possesses only doubtful value. This has been met with the statement that in cases where it was present there was an extensive transverse myelitis, but in the cases I have seen I am sure no such condition of affairs has existed. Of the three patients before you it will be found that in two this property

of the tendons is entirely absent, while in the third, the patient before you, it appears to be exaggerated. In one of these patients it will be seen that only one muscle is not involved, namely, the *vastus internus*. In that respect it illustrates Westphal's views, he having called attention to the exemption of this muscle. It is probable that the most important of the early symptoms of the first stage are those of a painful character. The first symptom is usually a sense of fatigue, which has associated with it pains of two varieties: 1st. Those which shoot down the back, the thighs, and the inner surface of the legs. Sometimes these pains proceed from below upward. They are the so called lightning pains, because of their violence and brief neuralgic character, and their intensity. 2d. Those which consist of a species of exquisite superficial hyperæsthesia, sometimes occupying a well defined space of variable extent. These spaces may be found at almost any part of the lower extremities.

Another early sensory symptom, which has been observed in the cases before you, in fact, is present in about two-thirds of all the cases, is pain in the back. After this, in constancy of appearance, comes the "constriction-band," a feeling which the patient compares to the sense of tightening which would be produced by a cord drawn about the body. This, it may be remarked, is not peculiar to locomotor ataxia, as has been stated by some authors, for it may also be a symptom of myelitis; and I have often seen it in connection with cases of spinal irritation, but in the latter disease it is apt to be situated higher up, and associated with disturbed respiration, while the constriction-band of locomotor ataxia is usually about the waist, or just below the border of the ribs. In the first stage there are other irregular sensory disturbances, such as visceral pains, joint pains, which are often mistaken by patients for subacute rheumatism, and certain affections of the eyes, notably of the ocular muscles, producing diplopia and strabismus. The duration of the first stage is variable. It may last for two or three years, or, as has been known in rare instances, it may extend for ten or fifteen years.

The commencement of the second stage is symptomatized by various disturbances of motility which you see markedly displayed in the patients exhibited to-day. The disturbance depends chiefly upon loss of muscular sense, connected very closely with the *anæsthesia* which occurs at the end of the first stage. It will be noticed that the gait of these patients is in no way suggestive of paralysis. It is rather the reverse, for the feet are planted widely apart, and the heel first touches the ground, while, as you know, the gait of the paraplegic patient is characterized, by dragging of the toe and inner side of the foot, and scraping the floor; while in the disease I will presently describe—lateral sclerosis—the toes drag over the floor; but there is a species of *talipes equinus* and great rigidity.

It will be found that in many patients the first indications of the existence of the disease is a worn condition of the back part of the heel of the shoe. The movements, as well as those of the upper extremities indicating the extension of the disease upward, or the formation of new foci of sclerosis, have recently been described by Onimus as an irregular expenditure of ill-directed force, a certain amount of the muscular power being expended in certain parts of an action when it is not needed. The will being actively exerted, the apparatus of execution and control are defective—and we may compare the individual to an engine with a broken governor or cut-off.

Later on, there is a species of paralysis which evidences extension of the disease into other parts of the cord. This is illustrated in the patient who presents the symptoms of the third stage of the disease.

When the disease has reached the second stage it will be noticed that there is a decided increase in the disturbances in walking, and the patient will be unable to perform even movements of the simplest kind. It is especially difficult for him to turn, as for retracing his steps. In a case which I have under observation in private practice, the patient becomes so much demoralized when crossing the street, by the approach of a wagon driven rapidly, that his legs refuse to support him and he falls to the ground.

In all these patients the voluntary control of the muscles is so imperfect that a fright of any kind will make them utterly helpless. During the first stage, or even before any sensory symptoms, there is usually developed a lesion at the fundus oculi. With the ophthalmoscope the optic nerve expansion will be found to be the seat of white atrophy.

This is one of the most important symptoms of the fully developed disease, although it is, as I have said, an early origin, and is well illustrated in the second patient presented. In the third case we have a picture presented which cannot be mistaken.

This woman suffers from decided optic nerve atrophy, and her pupils are contracted. She has the ataxic gait in a marked degree, and tactile sensibility is lost. In addition to other symptoms she presents one which is quite characteristic of the advanced stage of the disease, namely, pulmonary trouble, which has lasted for several years. In a large number of the cases, in fact, nearly all I have seen in which death took place, the termination is preceded by pulmonary tuberculosis, and I am convinced that in this disease, as well as in progressive muscular atrophy, the trophic cells of the anterior columns, the respiratory centres, and the roots of the intercostal nerves become involved, and in nearly all cases there is shallow breathing and weak action of the thoracic wall. With the exception of the ocular symptoms, which have already been mentioned, it is rare that any cerebral symptoms are manifested except it may be vertigo, which is sometimes present at the beginning of the disease.

In the case of the woman before you, there has been an upward extension of the disease, and probably brain involvement, as symptomatized by epileptoid attacks, which may be always safely considered as evidence of multiple lesion.

In these cases there is more or less mental disturbance. In fact, according to Obersteiner, and it has been my own experience also, a certain amount of mental trouble, sometimes only slight, perhaps scarcely recognizable, occurs in almost every patient of this kind. In the beginning, the temper of the person is very apt to undergo decided changes. She becomes morose and irritable, and is very liable to suffer from fits of mental depression.

This patient presents a discoloration in patches of the skin, which are suggestive of the existence of old herpes.

Skin lesions, whether herpes or pemphigus, have been shown by Charcot to be very frequently associated with locomotor ataxia, and I am inclined to think their value in connection with other spinal disorders is frequently overlooked. I have patients at present under treatment who, as soon as their spinal symptoms become at all aggravated, are subject to attacks, not only of herpes, but in one case there is a plentiful crop of acne upon the shoulders,

while the vertebral spines in the same neighborhood are quite tender upon pressure, and modifications in the course of the disease are expressed by a change in the eruption. I am unable, to-day, to show you a case which presents the joint enlargements sometimes seen well marked in the latter stages of this disease. It has been found, however, that various bone changes, such as atrophy, are not rare, and that the bones of these patients are very easily fractured. According to Charcot and Erb, joint enlargements begin at a very early stage of the disease. Muscular atrophy I need not tell you is a late complication, and is indicative of extension of the disease into the anterior parts of the cord. You will remember, then, that the disease has three stages; the earliest symptoms being those of pain in the back and the extremities, the latter of a shooting character, and often visceral colicky pain, sometimes with vomiting; that there is anaesthesia, especially of the plantar surfaces; that reflex action is, sooner or later, abolished, though to electricity it is increased; that the patients have a peculiar objective symptom, a sensation as though standing upon fur or some soft substance; that there is no loss of motor power whatever; that often the *tendon reflex* is abolished; that there are changes at the expansion of the optic nerve; that the patient gets a peculiar jerking walk, so that he is ultimately helpless, and takes to his bed; that he cannot stand with his eyes closed; that there are symptoms of general physical weakness; that obstinate constipation and bladder trouble are common in all stages; and that the termination in most cases is by pulmonary disease, cystitis, extension to the medulla, general exhaustion following bed-sores, or else the patient is carried off by some other disease. Although the term "progressive" has been used by some authors, it by no means follows that the disease does not have periods of remission. In the case of the woman before you, one year ago she was bed-ridden, while to-day she is able to walk with a cane. How long this condition of apparent improvement will last, I am unable to say, but such periods, of several months' duration, are by no means rare.

Etiology.—As to the cause of the disease in these patients, but little is known. In the first case, there is no history of a cause unless it may have been excessive venery, which I feel convinced has been too frequently assigned to an important place in the etiology of the affection. It is doubtless true that exposure to cold and dampness has more to do with the development of spinal sclerosis than any other influence perhaps, excepting alcoholism. Several of my hospital patients are sailors and laboring men, who are exposed in this manner.

Prognosis.—With reference to prognosis there is but little to be said. Recovery is exceedingly doubtful. The reported cures have probably been among patients in whom either diagnosis has not been made, or who have suffered from the disease in its early stages.

Treatment.—In the early stages of the disease I have used ergot with apparent good results, and I believe it to be more valuable in the treatment of inflammatory conditions of the nervous system than any drug at our command.

Later in the disease, a variety of remedies have been suggested, none of which possess any special efficacy, with the exception, perhaps, of phosphorus and cod-liver oil, the descending galvanic current and spinal cauterization.

For the relief of the pains, hypodermic injections of atropia, morphia, or muscarine, act most favorably.

For the same purpose the galvanic current may be used, the positive pole being placed over the painful point in the back, if such a point exists.

Warm sulphur baths, of a temperature not exceeding 90° F., are useful adjuvants.

They can be conveniently made by simply dissolving an ounce or so of sulphuret of potassium in water.

If, while treatment is being applied, certain symptoms are modified, do not be too sanguine with reference to ultimate results, for, in all probability, one of the remissions already alluded to has taken place. In some cases it is well to send the patient at once to a warm climate, for dampness and cold may greatly aggravate the sensory symptoms.

PRIMARY SCLEROSIS OF THE LATERAL COLUMNS OF THE SPINAL CORD.

The next patient brought before you is suffering from a very rare and interesting disease, known as primary sclerosis of the lateral columns of the spinal cord. You will find, by reference to your anatomy and the special works upon nervous histology, that the tract lying between the posterior and anterior nerve-roots contains three subdivisions. Lesions involving two of these subdivisions have been described by Tuerck, Fleischig, and others. The form of sclerosis which this patient undoubtedly suffers from invades that part of the lateral column lying in immediate contact with the anterior border of the posterior nerve-roots, and extends to the periphery of the cord. The lesion more commonly found is a secondary degeneration of the lateral columns, occupying a small territory in nearly the same situation; but the lesion does not extend to the periphery. It is separated from the cortex by the direct cerebellar columns.

Sclerosis of the lateral columns of the cord is characterized by entire absence of any sensory symptoms, which are so strikingly manifested in sclerosis of the posterior column, and illustrated by the three cases just shown.

The three marked symptoms of lateral sclerosis are loss of power, spastic muscular contractions, and exaggeration of the reflex activity of the tendons. As negative symptoms there is integrity of sensation, no atrophy, and no bladder or rectal trouble.

The patient before you, J. V. P., *et.* 28 years, and a native of the United States, gives no history of hereditary nervous disease. His family seem to have been healthy. About eight years ago, after a great deal of dissipation, he first noticed that he very easily became fatigued; that his legs felt heavy, and, if he persisted in walking, they grew stiff. He also staggered, stubbed his toes, and sometimes fell. He had good control over his bladder and rectum, and sensation was not affected, except that he occasionally experienced slight formication, but never *anesthesia*. There were no disorders of co-ordination, no cerebral trouble, and no sharp pains in the extremities. He however, gradually became helpless, and finally was obliged to use crutches. There was a strong contraction of the tendo Achillis, so that the ball of the toes touched the ground when walking; in other words, both feet were in the condition of *talipes equinus*, the toes scraping the ground at every step, while the feet became entangled with each other, in consequence of a forcible contraction or spasm of the adductor muscles of the thighs.

It will be noticed that his general condition is good. Although there is no vertebral disease present, you will observe, as he sits on the stool, that his body is permanently bowed to such an extent that a large transverse fold is made in the abdominal tissues.

This has been alluded to by Charcot as a common symptom in these cases. His legs are stiffly extended, he is unable to lift his heels more than a few inches from the floor, and he is utterly unable to rise from the sitting posture or to walk. As I strike the tendo Achillis, it will be noticed that the tendon reflex is present to a marked degree. In these cases, however, this symptom is variable, and sometimes a very slight excitation will cause violent movements. In other cases the condition of reflex excitability is so great that when the patient stamps upon the floor the entire limb shakes violently. You will also notice that, when I pass my finger ever so lightly over the abdomen, there is a convulsive upheaving of the muscles, and this I regard as of great importance as a diagnostic sign.

There is no atrophy of the muscles except what has followed disuse of the limbs. The atrophy which is present is general and not such as is found in paralytic atrophic diseases, where separate groups of muscles are affected, while others retain their normal contour.

The arms, you will notice, are not affected, and there is no cranial nerve paralysis whatever.

But very little is known with reference to this disease, for, altogether, less than forty cases have been reported. Men seem to be chiefly affected. In but one of the eighteen cases reported by Erb the upper extremities were affected by the disease. Like ataxia, it depends upon a decidedly slow process of degeneration, and most of the patients already observed have suffered from the disease for several years. So far no autopsy has been made which shows uncomplicated disease of the lateral columns. It is hardly fair to argue, as some have, that primary degeneration of the lateral columns is an unlikely lesion. It is possible, as we all know, for a certain group of spastic symptoms to be connected with certain lesions of the gray matter, but in every one of the cases brought forward the symptoms were by no means, classical and should be thrown out of the question. I do not see why primary degeneration of the lateral columns, or *tabes spasmodyca*, is not as likely to exist as a pathological entity as posterior spinal sclerosis or locomotor ataxia.

Etiology.—Very little is known with reference to the etiology of this disease. Betous reports cases which he believed to have been produced by metallic poisoning. Berger reports others occurring in patients of the same nationality and residing in the same region of country, and has made the inference that the disease is possibly due to some special climatic influence. These observations, however, have but little weight, for such cases have been observed in all parts of the world.

Diagnosis.—With reference to diagnosis, there is, at the present time, but little occasion for mistake. At first the disease was confounded with the form of sclerosis affecting both the anterior and lateral columns, and described by Charcot under the name amyotrophic spinal paralysis, but its distinct character was afterward recognized. Certain forms of hysteria with contractures may closely simulate the disease in question, but the violence of the symptoms and the sex of the patient will militate strongly against the chances of mistake.

Treatment.—With reference to treatment, I have only to repeat what has already been said in connection with the cases of locomotor ataxia. At my next lecture I will show you cases of secondary degeneration in the spinal cord, a disease which, in certain respects, resembles very strongly the case just presented.

Original Communications.

LARYNGEAL PHTHISIS.

By F. H. BOSWORTH, M.D.,

LECTURER ON DISEASES OF THE THROAT AT THE BELLEVUE HOSPITAL MEDICAL COLLEGE.

(Read before the County Medical Society, Monday, March 24, 1879.)

PART II.

(Concluded from No. 20, p. 463.)

THE diseased parts in laryngeal phthisis are extremely irritable and exquisitely sensitive, and the object should always be kept in view of accomplishing the treatment with as little irritation as possible. If then our medication can be deposited on the parts, without the instrument touching them by which they are conveyed, it is an end to be desired. The spray and powder insufflator accomplish this; the brush, the sponge, and the probe necessarily touch the diseased parts and are liable to do harm; the writer long ago abandoned their use from this consideration.

In a recently published work by Lennox Brown, of London, the use of sprays for making laryngeal application is condemned on the very surprising ground that they are unphysiological—an objection which unquestionably holds good, not only in regard to sprays, but also in regard to a large proportion of the procedures to which physicians are compelled to resort. He recommends the brush as preferable; one certainly fails to find any physiological precedent or justification for the introduction of the brush into the larynx where the introduction of fluids in a state of finely divided atomization is condemned. A pretty large experience in the use of sprays has so far convinced the writer of their superior efficacy over all other methods of applying medicated fluids to the upper air-passages, that he confines himself largely to their use; and in laryngeal phthisis, above all other diseases of the upper air-passages, the conviction is held that no other method is so little irritating, is so well tolerated, or is so efficacious. Pursuing the plan of treatment indicated above, it is the almost invariable rule that the applications are not only well, but gratefully borne, and followed by immediate relief to the subjective symptoms.

The above plan of treatment is for the stage of ulceration; the earlier stages of the disease are treated in the same way, with the omission of the use of iodoform, which, as stated above, is only used for its specific action in ulceration.

Inhalations, as a rule, are useless or of very limited efficacy in laryngeal phthisis. The volatile remedies which may be applied in this manner exercise so little of curative or controlling influence in this disease that their use is a waste of time; those remedies which are of most benefit by their local action cannot be volatilized. Lupulin, opium, cannabis indica, conium, and other sedatives are of some benefit in allaying pain, but it is limited. Benzoin, turpentine, creasote, and iodine, are, as a rule, too irritating.

Among the instruments in most frequent use in the treatment of laryngeal phthisis and other diseases of the upper air-passages, is the steam atomizer; this is an ingenious and attractive little instrument, but nevertheless an instrument of mischief. Its use is of undoubted benefit in many cases of acute inflammation of the fauces and neighboring parts; but it is extremely doubtful if it is of any service in the chronic forms

of disease; it encourages and promotes those features of catarrhal inflammation which it is the effort of the physician to control, viz., swelling, congestion, relaxation, distention of the blood-vessels, and hypersecretion. It is undoubtedly the hot steam which is the mischief maker, and it more than counterbalances the good that may be accomplished by the medicated fluid which it is used to atomize.

It is often desirable that the patient should have some method of using medicated solutions during the intervals of treatment; and for this purpose there is nothing better than the little Cologne atomizers, such as are found on many toilet-tables. The best of these is the Delano atomizer, with the long tube. It is sold in most drug stores. The fluid for use may be the carbolized alkaline solution given as a cleansing solution. To this may be added a sedative if indicated, such as a drachm of Magendie's solution to the ounce.

In the earlier stages of the treatment it is desirable that the patient be seen generally as often as every second day; but that should be governed by the duration of the relief which is given at each sitting. At the commencement it will often be necessary to give daily treatment; but if the progress of the case be favorable it will soon be necessary to repeat the treatment but once a week, or even in two weeks.

These measures failing to relieve or arrest the progress of the disease, the question of tracheotomy arises as a remedial measure in the earlier stages of the disease, before œdema with dyspnoea have occurred, which, of course, imperatively demand the operation.

The consideration which operates in favor of tracheotomy is the entire rest thereby secured to the larynx from the movements of phonation and respiration, thus putting the parts in the most favorable condition to get well. The consideration which operates against tracheotomy is the total ablation of a large and important part of the upper air-passages, by which the inspired air is rendered warmer, moister, and cleaner before it reaches the lungs. This consideration should never be lost sight of; and if the objection can be obviated by proper measures, which will occur to any one, it would seem that we have a resource which might more frequently be adopted. The operation is a simple one, and is rarely attended with any bad results due to the operation itself—such as shock, excessive hemorrhage, etc.

In Case II the operation was performed after six months of rather irregular attendance at the clinic without much relief. She lived four months with comparative freedom from the painful features of the later stages of laryngeal phthisis. The disease seemed to be arrested, and she died of the pulmonary disease.

In Case XXVIII the patient was a workman in a wire factory, his especial business being to temper the wire, an occupation which compelled him to breathe the irritating vapor from the tempering-pot. He asserted that all the workmen in the room with him suffered from throat disease and catarrh.

The direct cause of his laryngeal phthisis was his occupation. His health becoming impaired, he developed tuberculosis, being in the first stage only when first seen, though the larynx was in the advanced stage of the epiglottic form of laryngeal phthisis. He came to the clinic December 21, 1877, and was treated for three weeks with relief, when he disappeared. He was seen again about the middle of February, and found in a most deplorable state; his food was regurgitated, breathing and talking painful, swallowing almost impossible for food or drink, sleep broken and restless,

and cough almost incessant. There was no dyspnoea. Tracheotomy was done March 7th, and, although he was in an extremely weak condition, the operation was attended with no perceptible shock. He soon swallowed nourishment without pain, and fell into a quiet sleep, and passed his first comfortable night for two weeks. He lived eight days with comfort and comparative freedom from pain, and died on the ninth day of an attack of acute miliary tubercles, which carried him off in less than twenty-four hours. This attack was possibly brought on by the introduction of the tube, his surrounding being such as to interfere very much with the faithful carrying out of the directions as to the temperature of the room, moisture, attention to the tube, etc.

Of course remedies should be given to correct the general condition—cod-liver oil, iron, quinia, etc.—but it is not the province of this paper to discuss general medication.

A brief résumé is given of the cases on which these observations are based.

CASE I.—J. W., æt. 27, tinsmith, came to me September 1, 1877. Father died of phthisis. Has had more or less throat trouble for three years; has had bad cough for four months, with loss of flesh; has had severe pain in throat, with aggravation of cough and painful deglutition for two months. Lungs showed deposits and softening at each apex. Larynx: ulceration of true and false cords and commissure; epiglottis not involved. Under treatment four months; ulcer entirely healed; painful subjective symptom entirely relieved. Remaining chronic laryngeal catarrh.

CASE II.—A. Z., æt. 18, single, seamstress, came to me September 4, 1877. Family history good. Is well nourished and in apparent good health, but for two years has had throat trouble, hoarseness, and irritable cough; lungs healthy. Larynx shows chronic laryngeal catarrh, with the appearances described as the second stage of laryngeal phthisis, viz., thickening of the commissure and arytenoid, with gray infiltration on the laryngeal face of the interarytenoid fold. She developed extensive ulcerations, and grew worse gradually, and on March 1, 1878, tracheotomy was performed to relieve subjective symptoms, followed by marked improvement in symptoms, but she died of catarrhal phthisis in June, 1878.

CASE III.—M. G., New York, æt. 32; painter. Family history good. Came to me September 10, 1877, with a history of impaired health, with cough of two years' duration. I found him to be suffering from chronic catarrhal pneumonia of the right lower lobe, and also from Bright's disease. While under treatment he developed extensive ulceration of the laryngeal mucous membrane, by the different stages described, resulting in considerable loss of tissue, and attended with the usual subjective symptoms. The disease progressed unfavorably under the plan of treatment adopted, which consisted of the application of strong solutions of nitrate of silver, etc.; but when the milder plan described was begun he commenced to improve, and at the end of six months was completely cured. Died of acute œdema glottidis from Bright's disease.

CASE IV.—M. K., Ireland, æt. 40; foundryman. Family history good. Came to me November 10, 1877, with the history of a cough and progressive loss of flesh lasting for six months, and of serious throat trouble, with pain and distress in swallowing, for three months. There were deposits at the left apex. Larynx showed ulceration, involving arytenoid commissure and ventricular band; epiglottis not affected. He was under treatment for two months,

during which time the improvement was marked and most satisfactory, when he ceased his attendance at the clinic.

CASE V.—Thos. Conway, Ireland, æt. 46; coachman. Two brothers died of consumption. Came to me in January, 1878; spent much time in the stable, breathing the ammoniacal fumes from the stable-yard, and was conscious of its irritating his throat more or less. Six months before I saw him he caught a severe cold, and commenced to cough and suffer with painful deglutition. When I saw him he had deposits in both lungs, and the larynx was in the ulcerative stage of laryngeal phthisis. Epiglottis not involved. Under treatment he was relieved somewhat, but his attendance was irregular and he finally disappeared.

CASE VI.—G. C., New York, æt. 22; morocco factory. Family history good. While suffering from malaria in July, 1877, caught a severe cold, which was followed by cough and pain in chest; lost flesh and became very weak. In December commenced to suffer very much from distress in his throat, with pain on swallowing. In January came to me in a condition of great emaciation with an almost constant cough. Weight 98 pounds, his usual weight being 135. The lungs showed catarrhal pneumonia—right lower lobe; the larynx was in the stage of fully-developed laryngeal phthisis, the ulceration involving the true and false cords with the arytenoids and epiglottis, which was very much thickened. At the end of nine months' treatment the ulcerations were entirely healed. The patient increased from 98 lbs. to his normal weight again, and is virtually cured; the lung trouble has resolved; the cough has left him; there remains in the larynx the cicatrices of the old ulcers, with the little papillomatous growths which are so often found in laryngeal phthisis.

CASE VII.—M. K. II., Ireland, æt. 28. Family history good. Came to me January 12, 1878, with a history of severe cough for three months, and for one month pain and difficulty in deglutition, with regurgitation of food. Lungs showed deposit at left apex, with a few moist râles. Larynx showed third stage of laryngeal phthisis, the epiglottis being involved in the ulcerative process. Under treatment improved slowly, but surely, each sitting giving marked relief. Ceased coming after two months' attendance.

CASE VIII.—John Coffey, Ireland, æt. 37; wheelwright. Family history good. Came to me January 15, 1878, with a history of cough extending back for two years, and of troublesome throat symptoms of four months' standing. Examination showed chronic catarrhal pneumonia of the right lower lobe of the lungs, while the larynx showed infiltration of the mucous membrane of the right false cord, extending to the commissure and aryepiglottic fold, with small points of ulceration. Under treatment six months, with the result of entirely curing the ulceration, there remaining simply a moderate degree of chronic catarrhal laryngitis.

CASE IX.—Philip Bolger, Ireland, æt. 31; moulder. One brother died of consumption. Came to me with history of cough, with loss of flesh for two years; for two months has had serious trouble with his throat. Examination shows deposit of tubercle at each apex; softening and extensive cavities. Larynx in third stage of laryngeal phthisis, the ulcer involving false chord of right side and arytenoid commissure, with considerable thickening and infiltration of the parts. At the end of six months was entirely cured of the ulceration, and ceased coming. He died during the summer from a diarrhoea, with no return of any throat symptoms.

CASE X.—Mary Miles, Ireland, æt. 37; widow. Fam-

ily history good. Came to me February 1, 1878, with history of cough and loss of flesh of eighteen months' standing; for three months had considerable trouble with the throat, which was gradually growing worse. Examination of lungs showed cavities in left apex, with deposit at right side. Larynx showed arytenoids, commissure, and aryepiglottic folds swollen and infiltrated with ulceration involving right ventricular band and true cord. Was under treatment for five months, and was entirely cured. Died August 8th, with no return of throat symptoms.

CASE XI.—Kate Ward, Ireland, *æ*t. 33; married. Family history good. Came to me November 1, 1877, with a history of cough and loss of flesh dating back two years, while for six months she has been suffering more or less with the throat, and getting worse of late. Examination of lungs shows deposit at each apex, with softening on left side, and cavities. Suffering very much from the pain and distress in eating and drinking. Larynx showed thickening and infiltration, involving the arytenoids, commissure, aryepiglottic fold, and the epiglottis. Small points of ulceration on false chord and on crest of epiglottis. Under treatment nine months. Entirely cured of laryngeal phthisis; remains chronic laryngeal catarrh.

CASE XII.—Thos. McCaffray, Ireland, *æ*t. 41; maltster. Family history good. Came to me March 1, 1878, with history of lung trouble, as shown by cough, and loss of flesh of seven months' standing, and of throat symptoms of two months' duration. Examination of lungs showed deposit at left apex, with commencing softening. Examination of larynx showed second stage of laryngeal phthisis, not the fully developed ulceration, but gray thickening, involving arytenoids, commissure, and false chord. Under treatment four months. Entire relief of subjective symptoms, and arrest of the ulcerative process; a mild laryngeal catarrh remaining.

CASE XIII.—H. Higgin, Ireland, *æ*t. 39; porter. Mother died of phthisis. Came to me April 18, 1878, with the history of a hacking cough and irritable throat of two years' duration. Of late considerable pain and difficulty in deglutition; general condition bad. Examination of lungs failed to detect any trouble. Examination of larynx showed infiltrated condition of arytenoids, commissure, and ventricular bands, with small ulceration on left band, extending to arytenoid. Under treatment eight months. Ulceration entirely healed, and all subjective symptoms relieved; mild laryngeal catarrh remaining.

CASE XIV.—Andrew Patson, Ireland, *æ*t. 28; plasterer. Father and two sisters died of phthisis. Came to me May 8, 1878, with the history of lung trouble dating back three and a half years, and serious throat trouble for two months. Examination of lungs showed cavities in each lung. Examination of larynx showed the whole of the upper larynx involved in the ulcerative process, the epiglottis being much swollen; the subjective symptoms were of a very distressing character. The treatment gave considerable relief, and at one time he was quite free from pain referable to the throat. The lung disease progressing, he died October 15th.

CASE XV.—Amelia Bryen, New York, *æ*t. 20; single. Family history good. Came to me June 20, 1878, with history of cough of two years' duration, and throat symptoms of six months' standing, and, of late, very painful. Examination of lungs showed deposit at left apex, and commencing softening. Larynx: ulcerative process involving largely the whole lining membrane of the organ, the epiglottis being thickened and deformed. Under treatment there was some relief

and apparent improvement for a time, but it was not progressive. She ceased attendance.

CASE XVI.—John Allen, New York, *æ*t. 31; broker's clerk. Family history good. Came to me July 6, 1878. For eight years has had more or less cough; three years ago severe hemorrhage, which has recurred several times since. For a month has been suffering with his throat; deglutition painful and difficult. Examination showed deposit at left apex; larynx showed swollen condition of parts, with ulceration of left arytenoid, anterior face: the whole membrane coated with slimy and unhealthy looking mucus and muco-pus. Under regular treatment for two months with entire relief; since then comes in about once a month for treatment as his laryngeal catarrh becomes worse.

CASE XVII.—Frank Langly, Pennsylvania, *æ*t. 37; actor. Father, mother, and two brothers died of consumption. Came to me July 1, 1878. Had had lung trouble for a year, with more or less throat trouble for six months. Examination showed large cavities in each lung, with the larynx in the second stage of laryngeal phthisis, the parts being considerably thickened and infiltrated, though no fully developed ulceration. Under treatment he experienced almost entire relief from his painful throat symptom, though there remained considerable laryngeal catarrh.

CASE XVIII.—Wm. Singleton, New York, *æ*t. 29; shoemaker. One brother died of phthisis. Came to me in July, 1878. Lung symptom dating back three months, and throat trouble only one month. Examination shows deposit, with a few moist clicking râles at left apex, and the larynx in the second stage of laryngeal phthisis—the stage of infiltration. His attendance at the clinic was very irregular, though each sitting seemed to give relief.

CASE XIX.—H. F., New York, *æ*t. 31; clerk. Family history good. Had syphilis eight years ago, for eighteen months before cured. Has had more or less throat trouble for fifteen months, also a cough with expectoration; for two months throat symptoms worse. Came to me August 1, 1878. Examination shows deposit at apex of left lung, with some moist râles. Larynx in third stage of laryngeal phthisis. Epiglottis not involved. His improvement was very marked for a month, and then the lung symptoms becoming more aggravated, his progress was not favorable, and he finally ceased attendance.

CASE XX.—Mary Moran, New York, *æ*t. 22; single; teacher. Mother died of consumption. Came to me August 16, 1878, with history of cough of two years' duration; with loss of flesh; with throat symptoms of five months' duration. Examination showed phthisis, first stage, at left apex, and the larynx in the second stage of laryngeal phthisis, the infiltration being on commissure and left false cord. Her attendance at the clinic was very irregular, and her general condition was extremely unfavorable. She was given little relief.

CASE XXI.—James Welch, New York, *æ*t. 23; clerk. Family history good. Came to me August 19, 1878. For five months has had a bad cough; losing flesh; has night-sweats, etc. For one month has suffered very severely with the throat. Deglutition extremely painful and cough almost constant. Lungs: deposit at left apex, with moist râles. Larynx: arytenoids and commissures very greatly swollen, and the mucous membrane somewhat œdematous; the remainder of the lining membrane of the larynx being in a state of mild catarrhal inflammation. Attendance at clinic extremely irregular, for while each visit afforded him great relief, he would remain away two and three

weeks, and the disease progressed, involving the epiglottis and other parts. Not much improved.

CASE XXII.—Lizzie Juval, New York, *æt.* 21; single; saleswoman. Mother and sister died of consumption. Came to me August 16, 1878. More or less hacking cough for two years, though the general health has been good. For two months has been coughing badly; has slight hemorrhage; losing flesh; night-sweats; of late the throat has been giving much annoyance, deglutition being quite painful. Examination shows deposit at left apex, with a few moist râles while the larynx is in the second stage of laryngeal phthisis, the gray infiltration being on the face of the commissure, and extending to left ventricular band. Under treatment for two months the larynx cleared up, and there remains but a slight laryngeal catarrh, which is seen occasionally. Lung symptoms become latent, which I attribute to the local treatment.

CASE XXIII.—John Cahill, Ireland, *æt.* 28; shoemaker. One sister died of consumption. Came to me August 23d. For eight months, he said, he had been coughing, losing flesh, and having night-sweats. For three years has considered his lungs weak; for six months has had more or less throat trouble, which has been very painful for six weeks. Examination of lungs shows cavities in left upper lobe, with deposit in right side. Larynx in the third stage of laryngeal phthisis, the ulcerative process having extended to the epiglottis, which is markedly thickened. The case was a most pitiable one, and the suffering very great. Under treatment about three months, with relief, which was marked at times, but he gradually succumbed to the pulmonary trouble, dying on November 10th.

CASE XXIV.—Mrs. James A. Parker, Connecticut, *æt.* 38; married. Family history good. Came to me Oct. 6, 1878. During the winter of 1877 she had an attack of what her physician called broncho-pneumonia, from which she made but a poor recovery, her cough continuing, with the expectoration of frothy mucus. Six months before I saw her she commenced to suffer greatly with her throat, deglutition being extremely painful. She had been treated by the application of very strong solution of nitrate of silver, and when I first saw her was in a most deplorable state. The first application of the treatment described in the paper gave her the first absolute comfort and freedom from pain she had experienced in months. The progress of the case was very favorable until an attack of acute miliary tuberculosis caused her death early in December.

CASE XXV.—Wm. Daly, Ireland, *æt.* 33; clerk. Two brothers died of phthisis. Came to me October 15, 1878. Has had lung trouble for three years, and serious and painful trouble in the throat for four months. Examination shows cavities at left apex, and deposit, with softening, at right apex. The larynx in third stage of laryngeal phthisis, the epiglottis being involved in the ulcerative process. The treatment gave temporary relief only; attendance irregular at clinic; died this spring.

CASE XXVI.—Annie Forrester, Scotland, *æt.* 34; married. Family history good. Came to me Oct. 20, 1878. For three months has had cough, with expectoration, losing flesh, and having night-sweats. For three weeks has had painful deglutition, with constant sense of irritation. Examination shows deposit at left apex of lungs, with moist râles, localized. The larynx in the first stage of laryngeal phthisis, with slight grayish infiltration on laryngeal face of commissure. Under treatment the subjective symptoms were entirely relieved and the appearance markedly improved.

CASE XXVII.—John Halliday, Ireland, *æt.* 35; carpenter. Family history good. Came to me December 28. For two years had cough, with free expectoration, and occasional attacks of hæmoptysis; has lost flesh, and has had night-sweats. For two months has had more or less throat trouble, irritable condition, with some pain in swallowing. Examination of lungs shows dulness at left apex, with moist râles. Larynx shows first stage of thickening of commissure and club-shaped condition of arytenoids. Under treatment subjective symptoms improved, and for a month he has been free from any throat trouble. Still under observation.

CASE XXVIII.—James Gibney, New York, *æt.* 35; worker in wire factory. Family history good. Is a wire-temperer, an occupation compelling him to inhale the irritating fumes of the tempering-vat. As the result of this he has for several years had throat trouble. Came to me December 21, 1878, with a history of severe trouble in his throat for three months, with severe cough; for two weeks has had pain in swallowing. Examination of lungs showed dulness at left apex, with broncho-vesicular respiration, but very few moist râles, and the larynx in the third stage of laryngeal phthisis, with the epiglottis involved. Each sitting of treatment gave him much relief, but his general condition failing he was unable to attend the clinic, and all his symptoms growing so much worse, that on March 7th I performed tracheotomy to relieve the pain from which he suffered so much, being unable to eat, drink, or sleep. The operation gave immediate relief to the larynx, and his improvement was most satisfactory for eight days, when he succumbed to an attack of acute tuberculosis, within twenty-four hours of its onset.

CASE XXIX.—L. Turner, New York, *æt.* 23; married. Family history good. Came to me December 17, 1877, with the history of a neglected cold, two years before, developing into chronic lung trouble, and for three months she had suffered from pain and distress, referable to the larynx, with painful deglutition, etc. The lungs were in the third stage of catarrhal phthisis, with cavities at right apex; the larynx in the third stage of laryngeal phthisis, the epiglottis being involved in the ulcerative process. The treatment gave the most flattering relief to the subjective symptoms, and there was a decided improvement in the appearance by laryngoscopic examination; but an attack of acute miliary tuberculosis occurring four months after I first saw her, resulted in death six days after the onset of the attack, but the relief to the laryngeal symptoms remained.

This embraces only a portion of the cases seen, and only those which have presented conditions later than the first stage. All the bad cases are given as far as possible. Many cases have come to the clinic but once or twice, and of course no continuous record of them has been obtained.

The histories embrace 29 cases: in the second stage 8 cases; in the third stage, epiglottis not involved, 11 cases; in the third stage, epiglottis involved, 10 cases. Of the 8 in the second stage, 4 were cured, with a chronic laryngeal catarrh remaining; 4 simply relieved, irregular in attendance; all suffered from chronic pulmonary disease. Of the 10 in the third stage, with epiglottis unaffected: cured, 1; cured, with chronic laryngeal catarrh remaining, 6; relieved (on one of whom tracheotomy was performed), 4. In this group the disease was caused by chronic lung disease in 8; by syphilitic athenia, 1; by Bright's disease, 1; by anemia and occupation, 1. Of the 10 suffering from the epiglottic form of the disease,

2 were cured; one with chronic laryngeal catarrh, one with aphonia from cicatrices, and also a considerable trace of small warty growths in the larynx, due to the excessive cell-proliferation characteristic of the disease; on one I performed tracheotomy, with very marked relief; he died, however, on the tenth day from acute miliary tuberculosis; seven were only relieved somewhat of the subjective symptoms. Of the causes of the disease in this group, one was due to malaria and the direct effect of occupation—a tanner; and nine to lung disease.

Grouping the 29 cases: there were cured, 1; cured, with chronic laryngeal catarrh remaining, 11; cured, with aphonia from warts and cicatrices remaining, 1; relieved to a more or less extent, 16.

Of these 13 cases virtually cured of the laryngeal disease, 5 were in the third stage of tuberculosis, with cavities; 2 were in the second stage; 3 in the first stage; 1 had Bright's disease and chronic catarrhal pneumonia; 1 malaria; 1 chronic catarrhal pneumonia.

The points, in closing, that the writer desires to emphasize are:

1st. Laryngeal phthisis may develop from a simple catarrhal inflammation, if there exists an impaired state of health from any cause.

2d. The progressive stages are catarrhal infiltration, catarrhal ulceration, and follicular inflammation, and tubercle plays no part in its primary causation or development.

3d. The disease is far more amenable to treatment than is generally taught, especially if treated in the earlier stage.

4th. Tracheotomy is justifiable as a remedial measure, when local remedies fail to relieve, and before it is demanded by dyspnea from inflammatory stenosis.

PREVAILING DISEASES AND EPIDEMICS OF THE FIRST QUARTER OF THE YEAR 1879.

By JOHN C. PETERS, M.D.,

CHAIRMAN OF THE COMMITTEE ON EPIDEMICS OF THE PUBLIC HEALTH ASSOCIATION OF NEW YORK, AND OF THE COMMITTEE ON HYGIENE OF THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

From personal observation, conversation with many of the most prominent physicians, and communications from leading medical men, like Drs. Alonzo Clark, Austin Flint, Fordyce Barker, H. B. Sands, Abraham Jacobi, James R. Leaning, C. S. Wood, and many others, it has become evident that the health of this city has not been nearly as good as in 1877 and 1878; and has approached in mortality those unhealthy years 1875 and 1876.

The exact figures are: 7,576 deaths in the first three months of 1879; 6,664 in the same period in 1878; 6,002 in 1877; 7,633 in 1876; 7,842 in 1875; and 6,552 in 1874.

The principal cause for this variation in the mortality has been the mildness or severity of the winters. We had a mild winter in 1874; very severe winters in 1875 and 1876; mild winters in 1877 and 1878, and a long and rather severe winter, with much snow and ice, this year.

All the statistics have been supplied by Dr. Nagle, of the Bureau of Vital Statistics. The deductions are my own.

All are agreed that SCARLET FEVER has been the only severe prevailing epidemic, although a curious

minor plague—that of catarrhal inflammation of the eyes—is now going on.

There were 730 deaths from SCARLET FEVER in the first quarter of 1879; 317 in the same period of 1878; 293 in 1877; 245 in 1876; 186 in 1875; and 330 in 1874.

As 67 per cent. of the cases and deaths from scarlet fever occur in children under 5 years of age, and 24 more per cent., or 91 per cent. in all, happen in those under 10 years of age, it is evident that we must expect an epidemic of scarlet fever every five, seven, or ten years; unless this is prevented by cleanliness, isolation of patients; or, by disinfection, which must rival in care and minuteness the Lister method in surgical diseases.

Next in point of severity and frequency has been PNEUMONIA, which has nearly reached the epidemic proportions that it did in 1875 and 1876, and from the same cause, viz., the length and severity of the winter. The statistics are: 922 deaths in the first quarter of 1879; 833 in the same period of 1878; 753 in 1877; 946 in 1876; 1,071 in 1875; and 763 in 1874.

The allied diseases of pneumonia, viz., bronchitis, consumption, rheumatism, heart and kidney disease, have also been on the increase.

There were 434 deaths from bronchitis in the first quarter of 1879; 391 in the same period in 1878; 371 in 1877; 437 in 1876; 396 in 1875; and 349 in 1874.

There were 1,214 deaths from consumption in the first three months of 1879; 1,163 in the same months, viz., January, February, and March, of 1878; 1,054 in 1877; 1,123 in 1876; 1,188 in 1875; and 1,009 in 1874.

Rheumatism, which leads to heart, kidney, and lung disease, has been more prevalent this year than usual, doubtless excited by cold weather, and melting snow and ice. There were 398 deaths from heart disease in January, February, and March, 1879; 294 in the same months in 1878; 244 in 1877; 246 in 1876; 260 in 1875; and 216 in 1874.

Bright's disease, which is caused by exposure to cold and wet quite as much as it is by alcoholism and heart disease, caused 376 deaths in the first quarter of the year 1879; 282 in 1878; 270 in 1877; 327 in 1876; 296 in 1875; and 256 in 1874.

Whooping-cough is tending towards epidemic frequency. The statistics are: 219 deaths in the first quarter of 1879; 63 in the same period in 1878; 92 in 1877; 139 in 1876; 132 in 1875; and 107 in 1874. Whooping-cough, like scarlet fever and measles, prevails among the young, and we have to expect a new epidemic every five, seven, or ten years. Its danger is, of course, increased in cold weather, and absolute disinfection of all the expectoration and vomits is the only means that we have of staying its spread.

Measles, as has often been noticed before, is apt to lessen during the prevalence of scarlet fever. There were only 5 deaths in the first quarter of 1879, against 128 in the same period in 1878; 9 in 1877; 172 in 1876; 18 in 1875; and 94 in 1874.

Small-pox has almost been stamped out by better vaccination and re-vaccination by physicians and the Board of Health. There were no deaths from it in the first quarter of 1879; only 1 in 1878; 5 in 1877; no less than 194 in 1876; as many as 372 in 1875; and only 22 in 1874.

Diphtheria is steadily lessening, and its place is being supplied by a milder form of diphtheritic sore-throat. There were only 224 deaths from it in the first quarter of 1879; against 331 in the same period in 1878; 226, in 1877; no less than 725 in the same three months in 1876; 608, in 1875; and 308, in 1874.

The singular fact here protrudes itself that diphtheria is lessening in the face of an epidemic of scarlet fever, to which it so often allies itself; and in spite of severe weather, which so often precipitates it; and of greater filthiness of our streets, which so frequently aggravates all septic and malignant diseases. But the great nuisance of Hunter's Point has been abated, and also many minor nuisances, both on the east and west sides of the city. As diphtheria is also pre-eminently a disease of children, it is barely possible that an epidemic has run its course for the present, and may crop up again in severe proportions in the course of a few years, after a greater number of susceptible subjects have been born. But it is very evident that the same defects in sanitary arrangements in houses, which used to cause, or seem to cause, malignant diphtheria, now only excite a milder form of diphtheritic sore-throat, and follicular tonsillitis, which runs its course favorably in four to six days. I have seen diphtheritic sore-throat, repeatedly, in every floor of apartment houses, arising from sanitary defects in the cellar, which apparently would have caused diphtheria a few years ago.

The diseases of the spring, viz., *erysipelas*, *pyemia*, and *puerperal fever* have also been on the increase. Of these we only have statistics of puerperal diseases, which caused 104 deaths in the first quarter of 1879; 89, in 1878; 103, in 1877; 99, in 1876; 135, in 1875; and 116, in 1874.

Typhoid fever has been slightly on the increase. There were 104 deaths in the first quarter of 1879; 89, in that of 1878; 103, in 1877; 97, in 1876; 135, in 1875; and 116, in 1874.

Malarial diseases have caused 78 deaths in the first quarter of this year, mainly in the Twelfth, Nineteenth, and Twenty-second Wards, all of which are in the extreme upper parts of the city. But I have met with a severe case in Twenty-second Street, between Broadway and Fourth Avenue, in the person of a hypochondriac, who had not been out of the house for fifteen years, nor below the third story of that house; so that severe intermittent fever can evidently be generated in the middle of the city, either from exhalations from drain-pipes, or from the use of ice which has been collected from swampy regions, or from damp cellars, or from foul drinking water, or some other conjectural cause.

The greater quantity of snow and ice, coupled with great neglect in cleaning the street crossings, also caused almost an epidemic of fractures, dislocations, and bodily injuries from falls.

Changes in the weather are undoubtedly the great causes of mortality, viz., the extreme cold of winter, and the intensity of the heat of summer, and especially the rapid changes from one to the other.

Against these the people must protect themselves as best they can, especially against the extremes of cold, by proper diet and clothing.

It is almost impossible to calculate the number of cases of catarrh, pneumonia, pleurisy, rheumatism, croup, apoplexy, consumption, bronchitis, heart disease, kidney and uterine disease, which might be prevented by proper attention to bed and body clothing, both by night and by day.

For these the health authorities are blameless, and physicians and their clientele are culpable.

We may safely assume that the number of deaths from bronchitis, pneumonia, catarrh, influenza, croup, diphtheria, consumption, rheumatism, heart and kidney disease will attain its maximum in December, January, February, and March of each year; will decline somewhat in April, May, and June; reach their

minimum in July, August, and September; and again increase in October, November, and December.

But it may be safely stated that much malignant sore-throat, pneumonia, consumption, bronchitis, etc., may be produced by the simple inhalation of foul air in badly ventilated rooms and houses which are constantly pervaded by the smells of cooking, or from foul clothes and boots and shoes, or from unclean cellars and kitchens, drain-pipes, and from the aromas from foul streets, gutters, sewers, docks, and foul grounds.

In old times malignant and so-called typhoid-pleurisy, sore-throat, and pneumonia, were thus produced in vast epidemics, and they are not so very uncommon now, even in comparatively good-looking houses.

There is very little doubt, also, that much severe, obstinate, and even fatal, throat and lung disease is caused in delicate and susceptible persons by the very impure gas which is furnished by some of the gas companies.

Of the great class of infectious and contagious diseases, it is impossible to speak too highly of the exertions of the Board of Health, and physicians, and the populace generally, in the eradication of small-pox.

The great fever-nests have also been comparatively broken up, and typhus and typhoid fevers have long been reduced to their minimum, so that New York has often furnished fewer of these diseases than much smaller towns and even villages.

Diphtheria has diminished largely, either from unknown causes, or from a better preventive and curative treatment.

But there is every reason to fear that scarlet fever, measles, whooping-cough, have not been brought as much under the control of sanitary science as the progress of medical art has rendered possible.

Disinfection in these diseases is either not properly understood, or consistently enforced for a sufficient length of time, or else must be considered imperfect.

All these diseases progress most rapidly in badly ventilated houses, which are always infested with the smells of cooking, or from unclean persons or things.

Every excretion from the skin, nose, throat, lungs, stomach, bowels, and kidneys in these disorders, should be disinfected at once; the person, hair, and bed and body clothing, carpets, curtains, floors, walls, etc., must be cared for. And after this the patients, however well they may seem, should not be allowed to join their associates, at home or abroad, in churches, schools, or other places of assembly, until their persons and clothing are rendered absolutely free from infection.

For this physicians and parents are first responsible, but a large amount of proper advice and control is to be expected from the health authorities.

But the greatest amount of care by individuals and physicians will not prevent the spread of these diseases, as long as foul streets, gutters, sewers, etc., are allowed to poison the air.

That these have been shamefully neglected, there is not the slightest doubt, although the difficulty of removal of filth from the city is fully appreciated.

The enormous extent of our country, and the productiveness of much of its soil, seem to render the great bulk of city offal and manures valueless; to say nothing of the extreme offensiveness of garbage and street sweepings.

But it would seem that there are barren spots enough near the city, to render such products welcome if they could be transported with less expense and offence.

There are cities, however, which distribute all their street-sweepings and garbage to near barren lands with the best results; but it seems easier, if more wasteful, to dump them into the rivers, or tow them down to the sea, than to otherwise dispose of them. They can be made most useful and healthful on cultivated lands, but it is doubtful whether their deleterious qualities can ever be overcome if used to fill up low lands upon which dwellings are to be built, or to fill up streets or docks. However much these foul materials may be covered over with clean earth, or ashes, it is very probable, nay, absolutely certain, that such localities will remain forever unhealthy.

It seems not impossible that a good system of disinfection of garbage and street sweepings might be carried out at the dumping places, so that these naturally foul materials might be carried away by rail or boat.

There must be many places on our river, sea, and sound-shores to which such materials might be carried comparatively free of offence.

The pure unadulterated and offensive material is carried to some of the sandy wastes of Long Island, with profit, doubtless, by some wealthy persons; but with very great nuisance, which might easily be abated at a small expense, no greater than that caused by throwing a slight covering of clean soil over each open ear. This would absorb sufficient of the fertilizing material to pay for the outlay.

Progress of Medical Science.

TREATMENT OF PERTUSSIS.—In the treatment of this disease Birch-Hirschfeld speaks highly of inhalations of weak solutions of carbolic acid, combined with constant residence in a room whose air is kept loaded with carbolic-acid fumes by means of frequent sprinkling with a twenty per cent. solution of the acid. The patients should only be allowed to exercise in the open air for about an hour a day, and that only in fine weather. This treatment was first employed in the Blind Asylum in Dresden, where it proved very successful in a severe epidemic of the disease. None of the patients presented any symptoms of carbolic-acid poisoning while under treatment. During the first two or three days of the treatment no diminution in the number or violence of the convulsive attacks was noticeable; but after that an improvement invariably set in, the attacks becoming progressively less severe and less frequent. As a rule, the convulsive stage ceased after one week of the treatment; but in a few cases it dragged on into the second week. A slight bronchial catarrh usually persisted for several weeks. It was a noticeable fact in this epidemic that, when the sprinkling was discontinued on the fourth day, the attacks on all the patients under treatment at once became more frequent and violent, but again diminished in number and severity as soon as the sprinkling was recommenced. Birch-Hirschfeld has since employed this method of treatment in eighteen cases, some of them being in very young children, and in all the results were equally satisfactory. In one instance, in which a child one year of age and another two years of age were simultaneously under treatment, they were allowed to sleep in a room in which no carbolic acid was used; although the convulsive stage began with great violence in both of these cases, it lasted respectively only nine and eleven days.

Another method of treating the disease, which is

recommended by Dr. Neubert, of Leipzig, consists in the use of inhalations of a one per cent. solution of salicylate of soda, administered by means of a spray apparatus. He administers the inhalations every hour or two hours, the patient being placed in the horizontal position, and made to draw in deep breaths with widely-opened mouth. Dr. Neubert has only employed the inhalations in two cases occurring in the same family; but his success was so striking that he hastens to lay it before the profession. In both cases various methods of treatment had been tried for ten days; but the attacks were becoming more and more violent. Under the inhalations one of the children recovered very rapidly; in the other child the vomiting ceased immediately, and the attacks fell in five days from forty-eight to ten per diem, and disappeared entirely in four or five days. *Med.-Chir. Rundschau*, January, 1879, and *Jahrbuch. für Kinderheilkunde*, October, 1878.

ON TALALGIA AND ITS TREATMENT.—M. Bucquoy states that he has employed the salicylate of soda successfully in the treatment of that very obstinate affection characterized by pain in the calcaneum, which is not unfrequently met with in gony and rheumatic subjects. The affection is not attended by swelling or change in the color of the skin; but the pain produced by pressure on the central part of the heel is, sometimes exceedingly intense. He begins with one drachm of the salt per diem, increasing the quantity if necessary to two drachms, and even more. In large doses he states that it sometimes has a hypnotic action analogous to that of chloral.

M. Panas draws attention to the fact that the pain of talalgia is seated in the very centre of the heel, at a distance from the bursa mucosa of the tendo Achilles, and that it does not correspond to any important nervous twig. The pain is deep-seated, circumscribed, does not radiate into the lateral or posterior surfaces of the calcaneum, and seems to be located in the bone itself; it is sometimes, however, referred also to the articulations of the os calcis. M. Panas first met with the affection in a gonorrhœal subject. The rheumatic diathesis is the primary cause of the affection; as an exciting cause, he mentions the frequent pressure of the heel in the ground on walking.

M. Desprès regards talalgia as a malady peculiar to walkers; he calls it the "policeman's disease." Sometimes the patient is compelled to walk entirely on the front part of the foot, and a sort of *tabes equinus* is the result. M. Desprès treats the affection with punctiform cauterizations, morphine, arsenic, bromide of potassium, etc.; he also prescribes shoes so made as to disseminate the points of pressure. For the rheumatic element he has also administered the salicylate of soda in doses of about one drachm and a half per diem, but frequently without success.—*Lyon Médical*. No. 5, 1879.

HEMATINIC PROPERTIES OF DIALYZED IRON.—In the present state of the discussion as to the value of dialyzed iron, the experiments of Dr. Amory, the results of which are given below, will be of interest, as tending to define more clearly some of the effects of this drug. In five cases which presented very marked symptoms of anæmia, a careful estimate was made of the globular richness of the blood, and this observation was repeated at various times during the administration of the chalybeate under consideration. The results were uniformly an increase of the red globules, accompanied by a corresponding diminution of the subjective symptoms. In several instances, when the administration of the iron had been discontinued, or

had been irregular, a retrogression was observed by the hæmacytometer and reported by the patient. Dr. Amory does not claim that these observations are sufficient to settle the question, but he thinks they are encouraging, and he prefers this to the more astringent salts of iron. The solutions of dialyzed iron are not uniform; some are useless. That used in these experiments had a specific gravity of 1.042, and had no free acid.—*The Boston Medical and Surgical Journal*, April 3, 1879.

SYME'S AMPUTATION FOR CLUB-FOOT IN THE ADULT.—Dr. Stephen Smith reports a case of double Syme's amputation in the adult for club-foot, which was attended by excellent results. At the time of the first operation an attempt was made to save the left foot by excision of the cuboid bone, but was unsuccessful, the patient afterward asking for amputation. In presenting this case to the class Dr. Smith took occasion to urge the superiority of this operation over Chopart's or Pirogoff's, or amputation of the leg, as being a safer operation, and giving a more serviceable stump.—*The Hospital Gazette*.

ONE HUNDRED AND FIFTY OPERATIONS FOR EXTRACTION OF CATARACT.—Charles Higgins, F.R.C.S., presented to the Royal Medical and Chirurgical Society a report of 150 operations for extraction of cataract, of which 76.6 per cent. were successful, 16 per cent. partially successful, and 7.3 per cent. failures. One hundred and four cases were operated on by small flap, 25 by linear section, 21 by oblique corneal section. Iridectomy at the time of extraction, or as a preliminary operation, was strongly recommended. Mr. Macnamara said that he did not place much reliance on iridectomy, but advised the removal of the *entire* lens, if possible, without rupturing the capsule. In the prognosis he trusted much to the state of the pupil and its power of dilating under atropine. He had seen very perfect results from the old flap operation. Mr. Spencer Watson called attention to the method of operating by lacerating the capsule before the corneal section as offering less difficulty; also, the lens was less liable to be displaced into the vitreous humor. Iridectomy was generally advisable; he preferred the operation upward. Mr. Higgins agreed with Mr. Macnamara that the whole lens should be removed; but this was more easily done after iridectomy, which should be as small as possible. There is difficulty in removing the lens entirely in the early stage by the flap operation. He dislikes to introduce instruments beyond the anterior chamber. In most of his cases the upward section had been made.—*The British Med. Jour.*, March 15, 1879.

BLOOD CELL COUNTING.—Drs. Henry and Naucrede have furnished an interesting report of their experience in employing Hayem and Nachet's *hématomètre*, and Gowers's hæmacytometer. The principle of both these instruments consists in diluting a known quantity of blood with a known quantity of fluid and then counting the number of blood-corpuscles contained in a cell of a certain depth and superficies. Gowers's instrument was described by him as follows: "The hæmacytometer consists of (1) a small pipette which will hold exactly 995 cubic millimetres; (2) a capillary tube which contains exactly 5 cubic millimetres; (3) a small glass jar in which the dilution is made; (4) a glass stirrer for mixing the blood and solution; (5) a brass stage-plate carrying a glass slip, on which is a cell one-fifth millimetre deep, the bottom of which is divided into one-tenth millimetre

squares. Upon the top of the cell rests the cover glass. The procedure is very simple. 995 cubic millimetres of the solution are placed in the mixing-jar; 5 cubic millimetres of blood are drawn into the capillary tube from a puncture in the finger, and then blown into the solution. The two fluids are then mixed by the stirrer, a small drop placed in the centre of the cell, and covered by the covering glass. In a few minutes the corpuscles sink to the bottom of the cell, the number in ten squares is counted, and this multiplied by ten thousand gives the number in a cubic millimetre of blood. The average of healthy blood is 5,000,000 per cubic millimetre, or 100 in .00002 cubic millimetre or two squares (hæmic unit)." In experimenting with two of these instruments, Drs. Henry and Naucrede soon found that they behaved very differently, although the care taken to prevent error in manipulation was so great that it was impossible to attribute it to that source. Upon measurement, it was found that the cells were inaccurate, one being $\frac{1}{14}$ inch deep, the other about $\frac{1}{14}$ inch. The two cells were to each other as 5 to 7, and the difference in the count should therefore have been 40 per cent. In reality, there was only 15 per cent. difference, and the authors suggest as an explanation of this discrepancy that, *up to a certain point*, the depth of the cell has a direct influence upon the result; beyond this point the depth of the cell is of minor consideration.

In order to make the conditions of each count identical, the authors finally used a *ground glass cover*, which was marked so that the same side was always applied to the fluid. It is important to use the same cover-glass in the same position, because these glasses possess flaws and curves, and the discrepancies resulting therefrom may be very great.

The great source of inaccuracy, however, is in the measurement of the blood and diluting fluid. By counting a great number of squares, any inequality in the distribution of the corpuscles may be compensated for to a great extent, but in two successive measurements and counts of the same blood, an extreme variation of 790,000 per c. mm. was found. No one measurement of blood can be relied upon as trustworthy, but at least two should be made, and more if possible. Drs. Henry and Naucrede (both in perfect health) found 5,566,272.5 as the average number of red corpuscles in 21 counts for one, and 5,939,862.5 as the average of 26 counts for the other, the difference seeming to depend upon weight and size. It was also found by a series of experiments, that too much stress has been laid upon the manner of puncturing the finger so as to cause the flow of blood.

The authors can perceive no advantage in Gowers's instrument over that of Hayem and Nachet, beyond the facility it afforded for reckoning percentages, and this is more than counterbalanced by the greater ease with which counts are made in the smaller squares of Hayem and Nachet.—*The Boston Med. and Surg. Journal*, April 10, 1879.

A NEW MEDICAL JOURNAL.—*The Medical Herald* is the name of a new monthly forty-eight paged double-columned octavo journal lying upon our table.

It is published in Louisville, Ky., and edited by Dr. Dudley S. Reynolds, Professor of Ophthalmology and Otology in the Hospital College of Medicine, Medical Department of Central University. The journal is simply an enterprise of its editor, who aims to make it satisfactory to himself and interesting to his readers.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, May 24, 1879.

MALPRACTICE.

THE malpractice suit against the Manhattan Eye and Ear Hospital, of which we gave an account in our last number, has not only terminated favorably for the hospital, but it has also been the means of securing for the medical profession a decision which will protect it much more than it ever has been protected from unjust assaults. The counsel for the hospital, Mr. Wm. Allen Butler, made an elaborate argument for dismissal of the complaint.

This argument was based upon a decision given by the Supreme Court of the State of Massachusetts, which, in effect, decided that if a hospital had exercised due diligence in securing skilful and careful medical men for the treatment of its patients, it was not liable for any malpractice of which those medical officers might be guilty. Judge Lawrence reaffirmed this decision with regard to the State of New York. For the first time, therefore, in our history, hospitals are protected from suits of this kind, for it is not to be conceived that any respectable hospital will not exercise due diligence in securing careful medical officers. At any rate, in any such future suit, the only proof necessary will be that such was the case. In this particular instance the judge went further, and stated that there was no evidence to sustain the allegation of the plaintiff, but, on the contrary, there was overwhelming evidence as to the carefulness and skill of the surgeons. As we said last week, the profession is to be congratulated that there was no difference of opinion among its own members, the plaintiff being unable to produce a single medical witness to controvert the testimony of the medical staff of the hospital and other physicians who testified. Inasmuch as this decision involves very important points, and is of great interest to the profession, we have given it this extended reference:

The Manhattan Eye and Ear Hospital has been at the expense of securing this decision by engaging the

services of one of the most distinguished members of the New York bar to defend their cause. It seems to us that the other hospitals of the city might well consider the propriety of paying the expense of litigation, the termination of which has protected them from similar accusations. We should be glad to hear from the directors of the hospitals of this city upon this point, for the institution in question is poor and utterly without means to defray the expense of a trial that has been hanging over it for two years.

AMERICAN ASSOCIATION FOR THE CURE OF INEBRIATES.

THE American Association for the Cure of Inebriates held its last meeting in this city, May 13th and 14th. The attendance was not large, but the Association is composed of men who are thoroughly interested in the work, and who feel gratified with the progress which has been made in the diffusion of right ideas in regard to inebriety. The Association is based upon the view that inebriety is a disease as distinguished from the habit of excessive drinking, which is a vice, and that it is distinguished mainly by two features, periodicity and transmissibility. By periodicity is meant the tendency for the attack to occur at intervals, either regularly or irregularly; and by transmissibility is meant the tendency for the disease to be transmitted from parents to children. The Association holds to the doctrine, which it believes is confirmed by practical experience, that confirmed inebriates cannot, as a rule, cure themselves; that they must be kept out of the temptation to drink for a limited period, varying from a number of weeks to a number of months, or even several years. They hold that it is not practicable to put patients belonging to that class upon their honor, for the power of the disease is greater than the desire to keep a promise. There have been practical difficulties, both legal and professional, in the carrying out of the plans of the Association, just as there are practical difficulties in all new enterprises. The Binghamton Asylum, for various reasons, which need not be detailed, has not been a great success. These failures, however, are no discredit to the principle upon which the Association is founded, and which is believed to be sound in science, justified by results, and promises to be the universally accepted doctrine of the next century. The recent criticisms of Bucknille upon inebriate asylums in this country were partial and imperfect. Some of his statements are true, but they are not *all* the truth. They tell but one side of a complex subject. Some of the best and most successful institutions, like those in Chicago and Fort Hamilton, he did not visit. The results of experiments on the part of the Association during the last nine years seem to make clear the fact, that where proper State laws exist upon the subject, and in an asylum which is properly conducted, about one-third of the cases can be permanently cured. If this result shall be confirmed by the future, the showing, cer-

tainly, will be a most encouraging one. For in the treatment of insanity no such results are claimed; and of nervous diseases generally, take them as they come, functional and organic, under the best treatment of modern times, it is doubtful whether one-third are permanently cured. Statistics upon the subject, as upon all subjects, are liable to mislead the unwary. It is difficult to follow out the histories of those who leave asylums. But in some institutions especial pains are taken to keep upon the track of those who have been inmates, and information thus obtained is of scientific value.

It is to be hoped that the Association will continue its work until the true foundation of inebriety is touched and laid bare, so that not only the medical profession, but the entire people may be able to see it as it is and act wisely for its removal.

MEDICAL CERTIFICATES.

We have received a copy of *The Atlantic Review*, a very enterprising local paper published at Atlantic City, N. J., and devoted largely to advertising the unexampled advantages of that seaside resort. The present number is put forward as a climax of editorial enterprise in that it contains certificates from about three hundred Philadelphia physicians to the remarkable value of the place. The names, titles, and addresses of the doctors are given with great fulness, and the testimonials are written with a generous breadth of endorsement that reminds us of the grateful epistolary tributes to Hostetter's Bitters and Helmholtz's Bachu. One gentleman praises the air, another the sea, a third the accessibility of the place, and a fourth the baths. The remarkable effect of the resort upon children, especially in their second year, impresses itself upon a fifth, and all carefully add title and address to the testimonial. "Brain-wearied men and delicate females," "those suffering from chronic disease," "from loss of tone in the digestive system," from phthisis and bronchial complaints, from general debility, and those in convalescence, are all rapidly and surprisingly invigorated at this unassuming retreat. We are assured that the place has advantages much superior to those of the torpid and enervating climate of Florida. In fact, here at last is a place where the seeds of disease die out and the fires of youth are kindled again.

It is more or less pleasing, in this connection, to notice that this widely advertised three hundred—and the edition of the *Review* is an especially large one—does not include the Regulars alone. The Secretaries of two Homœopathic Societies join with the Professors in the Philadelphia colleges in hearty endorsement of the baths and boarding-houses, the atmosphere, the soil and the something, they don't know what, which destines Atlantic City to create an era in sanitary therapeutics. Bolus and globule act equally well here; regular and homœopath are em-

blazoned side by side in the enterprising columns of *The Review*.

Exactly why it was on or about April, 1879, that the piercing intellect of Philadelphia's three hundred medical men was thus moved to a simultaneous approval of Atlantic City, history will probably never know; but though the reasons for the date are obscure, the primary cause of the event has been told us. We quote: "The marvellous effect of the climate of Atlantic City upon their patients has induced these physicians for the sake of mankind to publish voluntarily over their own signatures [also their titles, addresses, and everything else but the office-hours] the proof of our city as a health resort. . . . It is the grandest thing that has ever been published in the history of the place. . . . We are glad to say that proprietors of boarding-houses are subscribing generously to this issue, and that others have promised to join in the good work." Now we suspected this on first glancing at the testimonials—and the office addresses. The love of mankind was at the bottom of all, a passionate yearning for the bettering of the race not to be controlled by the hackneyed and unsympathetic restrictions of the national code of medical ethics. This same sentiment is ever cropping out among our "eminent" men. We have had it in New York, and Appollinaris Water was the boon too great to go unendorsed. And so the Philadelphia doctors, unable to control the impulses of benevolence, have furnished the certificates to Philadelphia's Coney Island; "the sad, sweet music of humanity" rises in more cheerful strains, and "the grandest thing" in the history of Atlantic City has been accomplished. We trust it may be a pleasant memory to the three hundred, if patients fail and fees grow small, or when age comes on and the silent tomb is near, to feel that they have assisted in proclaiming to humanity, over their own signatures and addresses in full, the unspeakable advantages of Atlantic City, and in thus having created an epoch of no inconsiderable grandeur in municipal and boarding-house history.

More seriously, however, it seems as though this matter of endorsing medicines and health-resorts should be definitely attended to. There can be no doubt that it violates the code and is opposed to the general sentiment of the profession. The custom has been stopped here and in Chicago, but it is constantly developing itself again. Either it should be summarily put an end to, if possible, or consent to do it generally should be given, and to the latter alternative we do not believe the profession will agree. Once have it understood that a medical recommendation is a legitimate thing for a public journal, and no disciplining body can draw the line between proper endorsements and the most flagrant advertisements. There are too many of these Philadelphia gentlemen to make it possible to call them to account. It is not unlikely that some of the names are inserted unwarrantably;

and indeed they have placed themselves in a light that is quite as ridiculous as it is unprofessional. Nevertheless, such performances should not go unnoticed, and it will be extremely discreditable if they are repeated.

PREVENTION OF EPIDEMICS.

To guard against invasion by epidemic diseases is one of the duties of the present hour. Last year a large portion of our country was invaded by a pestilence which produced ravages more terrible, if possible, than those of war, and the medical profession has been stirred, since those eventful days, to renewed activity concerning quarantine regulations and general sanitation. We have had reason to be proud of the efficient quarantine that guards the entrance to this port, and have no cause for believing that in the future its vigilance will in the least be abated. There is one point, however, which seems worthy of mention, and that is the fact, lately brought to light, that if by any means an infected vessel once reaches the dock, there is no legal power by which it can be removed. A bill has been introduced into the State Senate, now in session, intended to remove this loophole of escape; and if it be true that there is no statutory provision to meet the exigencies of such an invasion, whether wilful or through apparently unavoidable circumstances, we hope our law-makers will lose no time in seeing that such a statute is provided—and provided in such shape that, if occasion arises, it can be executed without a moment's delay. It is a question that touches the vital interests of this port, of this State, and of adjoining States, and we trust the deficiency in the law will at once be remedied.

M'DOWELL, THE FATHER OF OVARIOTOMY.

At the Annual Meeting of the American Medical Association, held in the city of Detroit, Michigan, in 1874, Dr. J. M. Keller, of Kentucky, offered a resolution endorsing the action of the Boyle County Medical Society (Kentucky), and the Kentucky State Medical Society, toward the erection of a monument to Dr. Ephraim McDowell, of Danville, Ky., who was the father of ovariectomy, and performed his first operation in his own town in the year 1809. The resolution was unanimously adopted. At the Annual Meeting held in the city of Louisville, Ky., in 1875, the Special Committee, of which Dr. J. Marion Sims, of New York, was Chairman, and Drs. Washington L. Atlee, of Pennsylvania, W. T. Byford, of Illinois, and J. M. Keller, of Kentucky, were members, reported, among others, the following resolution: "Whereas, it is universally acknowledged that the late Ephraim McDowell, of Kentucky, was the originator of the operation of ovariectomy." Then followed resolutions devising plans for the establishment of the McDowell Memorial Fund, and remarks by Dr. S. D. Gross, of

Philadelphia, regarding the justice of the claims of Dr. McDowell to the origination of the operation, all of which was endorsed and adopted by the Association.

This is a brief history of the nucleus around which have since gathered the donations from the medical profession of this country, more especially of the commonwealth of Kentucky, and to-day we are able to chronicle the accomplishment of the work, and the erection of a suitable monument which confers "honor upon whom honor is due." The name of Ephraim McDowell, who was born in Rockbridge County, Va., November 11, 1771, performed the first ovariectomy in 1809, and died in the year 1830, will receive the homage due to a man who introduced one of the greatest surgical operations the world has ever seen, and one which has and will ever continue to bring unmeasured benefits and blessings upon woman. In the movement now represented by a plain shaft of granite, the medical societies of the State of Kentucky, the American Medical Association, and the members of the medical profession throughout the country, have done themselves lasting credit.

He did not live to be old; but the great question is, not how many years a man has lived, but how he has employed them. For an account of the proceedings upon the occasion, we refer our readers to the excellent report from our special correspondent.

Reports of Societies.

AMERICAN MEDICAL ASSOCIATION.

THIRTIETH ANNUAL MEETING,

Held in the City of Atlanta, Ga., May 6, 7, 8, and 9, 1879.

REPORT OF SECTIONS.

SECTION ON PRACTICAL MEDICINE, MATERIA MEDICA, AND PHYSIOLOGY.

DR. THOMAS F. ROCHESTER, of Buffalo, N. Y., Chairman.

DR. W. C. GLASGOW, of St. Louis, Mo., Secretary.

TUESDAY, MAY 6TH—FIRST DAY.

The Section was called to order at 3 P.M. by the Chairman.

The first paper read was by DR. N. S. DAVIS, of Chicago, Ill., and entitled

CLINICAL AND METEOROLOGICAL RECORDS.

The object of the work of obtaining clinical and meteorological records was to obtain the actual etiology of acute diseases. Dr. Davis has been an active worker in this department, and his present report was a continuation of that already made to the same Section at the annual meeting held in Chicago in 1877 (see MED. RECORD, vol. xiii., p. 378). Beneficial results were still being obtained, and the field of observation was widening.

The paper was referred to the Committee on Publication.

EXPERIENCE OF CONSUMPTIVES IN COLORADO, AND SOME OF THE AËRO-HYGIENICS OF ELEVATION ABOVE THE SEA, WITH CONCLUSIONS,

was the title of a paper written by Dr. CHARLES DENISON, of Denver, Colorado, and presented by Dr. John P. Logan, Chairman of the Committee of Arrangements.

Some difficulty being experienced in reading the paper, the reading, on motion, was discontinued, and the further consideration of the subject was postponed until 3 P.M. on Wednesday.

The Section then adjourned to meet on Wednesday May 7th, at 3 P.M.

WEDNESDAY, MAY 7TH—SECOND DAY.

The Section was called to order at 3 P.M. by the Chairman.

The first order of business was a continuation of the paper on "Aëro-hygenics of Elevation above the Sea," by Dr. Denison, of Colorado.

Dr. DENISON asked that the Section recommend the Signal Service Bureau to prepare charts to be published with his paper, and on motion his request was granted.

The motion to refer the paper to the Committee on Publication gave rise to discussion, but the paper was finally so referred.

ON THE USE OF WATER IN THE TREATMENT OF DISEASES OF THE SKIN,

was the title of a paper read by Dr. L. D. BULKLEY, of New York. It contained the results of the large experience of the author in the use of water in the form of spray, baths, affusions, etc., etc., more especially in the treatment of chronic diseases of the skin. It was discussed by Drs. F. P. PORCNER, of Charleston, S. C., and J. V. SHOEMAKER, of Philadelphia, Pa., and referred to the Committee on Publication.

ADDRESS BY THE CHAIRMAN.

The Chairman's address before the Association in general session was presented by the Secretary.

Dr. T. B. LESTER, of Kansas City, Mo., was called to the chair.

Dr. T. S. HOPKINS, of Augusta, Ga., moved that the address by the Chairman be referred to the Committee on Publication. The motion gave rise to discussion, which was participated in by Dr. LYON, of New Orleans, who made special reference to the portion recommending the establishment of a national quarantine as a preventive of yellow fever. He said that the treatment of yellow fever was as well understood as was the treatment of any other serious disease; that yellow fever did originate in New Orleans, and that there was never a year that there was not yellow fever in that city that originated there. Dr. Lyon contended that quarantine laws did no good, and as proof he said, that during the late war, when there was not and could not be any communication between New Orleans and the West Indies, there was not a single year but there were cases of yellow fever in New Orleans.

He contended that the disease was not contagious, and that it would in future, as it had done in the past, continue to originate in that city. He believed in local sanitary measures instead of the quarantine.

Dr. HOPKINS, of Georgia, agreed with Dr. Lyon that yellow fever was of local origin, and that quarantine regulations were useless in preventing the disease.

Dr. BROWN, of Texas, asked Dr. Lyon if quarantine did not keep the fever out of Texas.

Dr. LYON replied that it did not, and asked the gentleman why it did not keep it out of Jackson, Mississippi, which was surrounded by men armed with shotguns.

The question was not answered.

Dr. A. W. DE ROALDES, of New Orleans, said that in a large majority of years yellow fever originated in New Orleans. He believed that proper sanitary measures would prevent epidemics in that city. He did not favor a national quarantine law.

Dr. ROCHESTER said he had not treated a case of yellow fever in twenty-eight years. He did not doubt that there were occasional cases occurring sporadic in New Orleans, but he believed that the quarantine would prevent the terrible epidemics.

Dr. FOREMAN, of the U. S. A., said that while the fever might originate in New Orleans, there were cities where it did not originate, and we needed the quarantine against the places in which the fever originated.

The motion to refer the address to the Committee on Publication was carried.

The Section then adjourned to meet on Thursday, May 8th, at 3 P.M.

THURSDAY, MAY 8TH—THIRD DAY.

The Section was called to order at 3 P.M. by the Chairman.

The first paper was read by Dr. G. F. COOPER, of Georgia, and entitled

VERATRUM VIRIDE AND ITS USES.

It was an elaborate résumé of what was known concerning that drug and its uses. On motion it was referred to a sub committee to be appointed by the Chairman.

Dr. W. C. GLASGOW, of Missouri, followed with a paper on

PLASTIC BRONCHITIS.

A review was made of the literature of this subject, and several cases were reported which had fallen under his care and observation.

On motion, the paper was referred to a special committee to be appointed by the Chairman.

INFLAMMATION OF THE HAIR-FOLLICLES OF THE BEARD,

was the title of a paper read by Dr. J. V. SHOEMAKER, of Philadelphia, Pa. The peculiar features of the affection were dwelt upon, and certain points in relation to differential diagnosis were fully considered.

The paper, on motion, was referred to a special committee to be appointed by the Chairman.

There being no further business before the Section, it adjourned.

SECTION ON OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN.

Dr. E. S. LEWIS, of New Orleans, La., Chairman.
Dr. ROBERT BATTEY, of Rome, Ga., Secretary.

TUESDAY, MAY 6TH—FIRST DAY.

The Section was called to order at 3 P.M. by the Chairman.

TUBO-OVARIAN GESTATION (CASE) OPERATION AT THE FIFTH MONTH—DEATH,

was the title of the first paper, and read by Dr. ROBERT BATTEY, of Ga. The paper consisted of a detailed account of the clinical history, the diagnosis, the operation, and the autopsy. At the request of the

author, it was withdrawn from the Section, with permission to publish in some medical journal.

Dr. Battey employed the écraseur to open the sac, and believed it to be the best instrument that could be employed, not excepting the galvano-cautery. He believed that the treatment of extra uterine gestation could not be governed by any fixed rules.

ELECTROLYSIS OF FIBROIDS

was the title of a paper presented by Dr. E. CUTTER, of Massachusetts, and read by Dr. Dunster, of Michigan. It was merely an appendix to a paper read before the same Section at its meeting in Buffalo, 1878, and published in the *Am. Journal of Med. Sciences* in the same year. [See *MEDICAL RECORD*, vol. xiii., p. 493.] It was referred to the Committee on Publication.

LACERATION OF THE PERINEUM—TREATMENT BY KEEPING THE BOWELS OPEN, INSTEAD OF CONFINED, AFTER THE OPERATION.

The regular business before the Section having been transacted, the Chairman called upon Dr. E. S. DUNSTER, of Ann Arbor, Michigan, to suggest some subject as a topic for discussion. Dr. Dunster responded by announcing the above, and remarked that Dr. Thompson, of Washington, had drawn attention to that plan of management by a report of favorable results obtained in fifty-four cases—in no one instance had there been failure to get good union. About two years ago Dr. Dunster had occasion to operate on a case of complete rupture of the perineum, and, as a part of the preparatory treatment, ordered a laxative. The patient, by some mistake, took an overdose, and the consequence was that during the operation there were fluid discharges flowing from the rectum. After adjusting the sutures and bringing the cut surfaces into apposition, he noticed the *absolute absence of any strain upon the line of the wound* when a fecal evacuation occurred. The case did well.

He operated upon the next case according to the old plan, and the wound, notwithstanding the care of a skilled nurse, tore open when the first movement of the bowels took place. Dr. Dunster then related two cases in which the bowels remained loose during the after-treatment, and in which complete success was obtained. In one there was a large rectocele, and the patient had from one to three fluid movements, daily, from the bowels. The stitches were removed on the ninth and tenth days, and although the pain and nervous excitement were quite irritating, the union was perfect and the success was good.

He had become convinced that, upon the whole, of course there were exceptions, it was a wiser and a safer method than the plan of constipating the bowels.

Dr. M. A. PALLEN, of New York, remarked that the plan of securing looseness of the bowels after operation for rupture of the perineum, was the one which he had adopted for many years. He had recommended the plan in a paper published in 1874, and renewed the recommendation in a paper published in 1875.

Dr. KING, of Pittsburg, suggested that tincture of opium could be combined with a saline cathartic, and in that manner both soluble bowels and relief from pain and nervous excitement could be obtained.

Dr. ALBERT H. SMITH, of Philadelphia, remarked that, upon theoretical grounds there was great force in Dr. Dunster's remarks. His experience, however, did not confirm the claimed value of the method, although he wished that it might.

Dr. DOWELL, of Texas, believed that all the diffi-

culties alluded to might be avoided by administering a full enema just before removing the sutures. Discussion was continued by Drs. Taliaferro, of Georgia, Cole, of California, and Parvin, of Indiana.

Dr. M. A. PALLEN, of New York, then presented

A NEW FORM OF PESSARY

for the correction of uterine displacements.

Dr. H. F. CAMPBELL, of Augusta, Ga., exhibited a modified stem pessary.

The Section then became agitated upon the subject of pessaries, and discussion was continued until the lateness of the hour disappointed a number of speakers.

The Section then adjourned to meet on Wednesday, May 7th, at 3 P.M., and the subject of pessaries was made a special order.

WEDNESDAY, MAY 7TH—SECOND DAY.

The Section was called to order at 3 P.M. by the Chairman. The minutes of the previous meeting were read and approved.

NEW INSTRUMENTS.

Dr. H. O. MARCY, of Boston, Mass., exhibited and described Jennison's exploring and indicating sound in its complete form. [See *MEDICAL RECORD*, vol. xiii., p. 493.]

Comments were being made upon the instrument, when the Secretary submitted that it was *patented*, and therefore had no right in the Section. The Chairman decided the point of order well taken.

Dr. MARCY also exhibited Dr. Chadwick's gynecological table, and described its convenience and variety of use.

TREATMENT OF UTERINE DISPLACEMENTS BY THE STEM PESSARY

was the title of a paper presented by

Dr. E. CUTTER, of Massachusetts, and read by the Chairman. The author recognized the dangers attending the use of an intra-uterine pessary, but believed that there were cases in which the displaced organ could not be held in position by any other form of instrument. The stem pessary employed by him was ordinarily about two and a quarter inches long, sometimes shorter, and was attached to a hard-rubber elbow that was held in place by a band passing around the body of the patient.

The paper was referred to a sub-committee, consisting of Drs. Dunster, of Michigan; A. H. Smith, of Pennsylvania; and Cross, of Arkansas.

NEW INSTRUMENT FOR OPERATION FOR VESICO-VAGINAL FISTULA, WITH CASES.

Dr. E. B. TURNIPSEED, of South Carolina, read a paper upon the above subject, which drew the thanks of the Section, and was referred to the Committee on Publication.

The instrument, when complete, embraced a few self-retaining speculum, retractors, large apparatus (used in stitching) bearing a smaller comb-shaped apparatus set with needles, which were clamped when the operation was completed; curved needles, gold triple plated with hard-rubber clamps, with springs; trimmers, dilators on the principle of changeable valves, and a hysterotome.

IMPROVED METHOD OF OPERATION FOR LACERATED PERINEUM.

Dr. M. A. PALLEN, of New York, illustrated, by means of diagrams, his method of operating for lacerated perineum, which consisted essentially in

transplantation of the flap dissected up so as to lengthen the vagina.

KOLPOKLEISIS IN A CASE OF PROCIDENTIA.

DR. PALLEN also described this operation, and illustrated it by means of diagrams.

VAGINO CERVICPLASTY.

DR. PALLEN also described and illustrated a plastic operation involving the vagina and the cervix, and as a substitute for amputation of the cervix uteri. The possibility of the operation had been denied by Dr. Emmet, because of the non-existence of elongation of the cervix uteri in the nonparous woman. To the operation Dr. Pallen gave the name vagino-cervicplasty, and recommended it for certain cases of apparent cystitis, painful coition, etc., when the cervix dipped into the vagina one inch anteriorly, and perhaps an inch and a half or an inch and three-fourths posteriorly. He discussed the subject at great length.

The Section then adjourned, to meet on Thursday, May 8th, at 3 P.M.

THURSDAY, MAY 8TH—THIRD DAY.

The Section was called to order at 3 P.M. by the Chairman. The minutes of the previous meeting were read and approved.

DR. BARTLETT, of Wisconsin, was called to the chair, and the Section entered upon the consideration of the

ADDRESS OF THE CHAIRMAN.

DR. A. H. SMITH, of Philadelphia, alluded to

CHANGE OF PRESENTATIONS AND POSITIONS OF FŒTUS prior to labor. Those changes could in many cases be effected with ease and advantage. His efforts to convert a posterior position of the occiput into an anterior one, and maintain it, had been uniformly abortive. There was something peculiar in those cases which made them very obstinate. He did not bandage the abdomen after turning the child in utero.

LIGATION OF THE CORD.

DR. SMITH thought that the question whether the cord should be ligated early or late after labor was an unimportant one. His practice was to ligate it as soon as pulsation ceased.

PROLAPSE OF THE CORD.

DR. H. O. MARCY, of Massachusetts, referred to Dr. Gairdner's method of treating prolapse of the cord by rotating the child in the uterus, thus winding the funis around its body.

DR. MORRIS, of Ohio, doubted the propriety and the success of turning in the eighth and ninth months.

DR. LEWIS, Chairman, explained that the manipulation was effected with greater ease and safety than in the earlier months of pregnancy.

The address was referred to the Committee on Publication.

On motion by DR. WARNER, of Boston, Mass., the Section requested Dr. Buttey to return his paper on tubo ovarian pregnancy to its custody, and referred it to the Committee on Publication.

PESSARIES.

The discussion on pessaries was opened to-day by DR. A. H. SMITH, of Philadelphia. He made special reference to the action of the posterior ligaments—the broad, the lateral, and the anterior ligaments of the uterus—and spoke in high terms of the theory underlying the efficient Hodge pessary.

DR. PALLEN, of New York, took issue with Dr. Smith, and claimed that no man had ever found at post-mortem a condition of ligament that would permit displacement of the uterus. There was no such thing as a ligament of the uterus. The term was a misnomer.

The etiology of displacement was *primarily*, derangement of the pelvic circulation; *secondarily*, laceration of the perineum or other conditions which removed sustentative circumferential support; and, *thirdly*, purely mechanical influences acting from either above or below. He denied the possibility of displacement occurring as the result of straining upon an inflamed ligament.

Dr. Pallen continued the discussion at great length, after which the Section adjourned.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, May 1, 1879.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

(Continued from No. 20, p. 478.)

POSTURE OF THE PATIENT.

The next point to consider was, what position of the patient was most favorable for the operation of internal traction. As a rule it should be one which would permit the viscera to gravitate toward the upper part of the abdomen, provided such a posture would not interfere with advantageously employing taxis and flexion, adduction, and rotation of the thigh. Practically, however, there was rarely or never any difficulty in combining these various desiderata, although the writer was of the opinion that the value of the aid rendered by getting the thigh in the position just mentioned had been greatly overestimated. Even a slight elevation of the hips (such as placing them upon a pillow, for instance), was all that was necessary in many instances, since this was sufficient to cause withdrawal of the viscera to a considerable extent. The raising of the hips upon the shoulders of an assistant, as in one of the cases before narrated, was recommended by some, while Prof. Gross advised that the patient should be turned over upon the opposite side from the hernia. Mr. Winslow advocated the knee-elbow position while taxis was being made, according to the practice of some gynecologists in uterine displacements. Finally, it was sometimes desirable to place the whole body on a steep inclined plane with the head downward, as had been done in Number Three and others of Dr. Hamilton's cases. The writer mentioned that this procedure was of old date, and gave a brief sketch of its history. One of the best authorities, Percival Pott, had said that the nearer the patient's position was to that of a man standing on his head, the better. Velpeau, although not attaching any great importance to such a posture, plainly stated that Laurence was in error in holding that no change was thereby caused in the position of the viscera, in consequence of their being so tightly packed in the abdominal cavity, and acknowledged that the procedure did not deserve the oblivion into which it had fallen, or the ridicule which had been bestowed upon it by some. When such were the views of Laurence, it was natural that he should be of the opinion that it was impossible for the measure to be of any service, and Bryant also believed it to be useless, as did Sir Astley Cooper. Dewitt, Erichsen, Gross and Ashurst, on the

contrary, all spoke more or less favorably of it. It was doubtless true that it would fail in a certain proportion of cases, but nevertheless Dr. Hamilton could not but regard it as a fact that this method, in conjunction with judicious taxis, gave better results than any other at present known to science. It had been offered as an objection to it that the inverted posture would be likely to do harm by exciting inflammation; but this held true much more in regard to taxis than it. He had never known it to give rise to pain; while this could not always be said of taxis. In the early stage of strangulation, withdrawal of blood from the part was undoubtedly of service, and it was then that leeching, the application of ice, etc., might prove useful; but if this were the case of all, the more benefit would the inverted position be. There was also this additional advantage about it, that there was no danger whatever of its being followed by gangrene, which had been known to result from the application of ice when maintained for too long a period. There was never, really, any need to keep up the use of ice long, however, since if it did not act promptly there was no hope of its doing any good at all.

After a careful consideration of the subject, and an extensive practical experience in regard to it, Dr. Hamilton's conclusions were as follows:

1. Hernial apertures are not under the control of the muscles.
2. Posture does not relax the apertures when the seat of the hernia is in the sac itself, nor when it is at the internal ring in inguinal hernia.
3. Neither warmth nor cold, nor any other sort of local application, are capable of relaxing these apertures.
4. Neither do chloroform or other anæsthetics affect hernial apertures, except, perhaps, in cases where the hernia is very recent.
5. In short, hernial apertures can seldom be affected at all by any means brought to bear upon them, whether local or general; but this is not requisite for relief, since the strangulation is not the result of contraction of these apertures, but of the pressure of the distended hernia upon them.

A second series of conclusions in regard to the postural method of treatment were as follows:

1. Taxis is of prime importance.
2. Internal traction is only second to this in value. It is to be effected by securing the paralysis of the abdominal muscles and exciting peristalsis in the intestine.
3. Chloroform, hot-baths, and other similar agents are the best means for accomplishing muscular relaxation, peristalsis, and anti-peristalsis.
4. Ice can only relieve the "button-holing" when this is due to congestion, and when it is applied very early. Opium is also of a somewhat limited application.
5. Emetics may be of service by causing an upheaval of the viscera, and also, probably, by exciting peristalsis.
6. Purgatives act by causing peristalsis above, and anti-peristalsis (sometimes) below the seat of stricture.
7. Stimulating enemata and enemata of tobacco also induce peristalsis, and are both direct and indirect in their effects.
8. All positions of the patient are beneficial in which the viscera are drawn upward; and that is likely to be of the most service which causes the most efficient inward traction, at the same time that it does not interfere with the application of taxis.

PROF. ALFRED C. POST being called upon to open the discussion, said that the strangulation was due to

a want of proportion between the size of the canal and of the protruded parts, and he agreed with the author of the paper in the statement that it was not the result of contraction of the apertures, but rather of the pressure of the distended mass upon the apertures. It was a well-known fact that hernias did not, as a rule, become strangulated when they were recent. There was one variety, however (not to speak of traumatic hernia), in which the strangulation occurred simultaneously with the hernia itself. This was the congenital form, in which the *tunica vaginalis*, owing to a want of adhesion between its sides, remained open above, and so continuous with the abdominal cavity until adult life. Many years ago the first case of this kind which had been recorded in New York came under his care at the New York Hospital. It occurred in a seaman in consequence of his straining himself while working at the capstan, and the condition had lasted for three days when he was brought to the hospital. There was a tumor in the rectum which resembled very closely the ordinary swelled testicle, and there was a good deal of discussion among the surgeons in regard to the diagnosis. Of the six or eight who saw it, no one agreed positively with him (Dr. Post) in the opinion that it was a strangulated congenital hernia.

Dr. Valentine Mott refused to accept the statement of the man that the trouble originated from a strain, and believing that it was really due to a blow from a capstan-bar, pronounced it a case of traumatic swelled testicle. Notwithstanding this opinion, however, Dr. Post performed an exploratory operation, when his diagnosis was confirmed; but the interference was too late, and death soon resulted from peritonitis. He was told that, in speaking of the case afterward, before his class, Dr. Mott stated that he himself had *judged* wrong, and that a certain young surgeon had *guessed* right. Prof. Knight, of New Haven, also told him of a similar case, and he mentioned this variety of strangulation on account of the bearing which it had on the question of operation.

While in recent hernias the apertures were small, in the old ones they had become large; but still at the time of strangulation the protruded part increased in size, out of proportion to even these enlarged apertures. As regards the matter of reduction, he thought that there was no question about the advantage of the pulling process over one of pushing; just as it was much easier to pull a large thread through the eye of a needle when one had once gotten hold of the end of it, than it was to push it through at first. Some years ago a case of ordinary strangulated hernia was brought to the New York Hospital, and Dr. Kearney Rodgers was about to operate before a class of students, when he (Dr. Post) asked that he might first try the effect of inward traction. A stout man was directed to raise the patient's hips upon his back, by carrying his knees across his shoulders, when in a few minutes the hernial tumor entirely disappeared. Since then he had seen many similar instances. He did not wish to throw any discredit upon the method of taxis, however, as this was often of the greatest assistance, in conjunction with the postural treatment.

When the protruded part was distended with gas, acupuncture was often of the highest service; and when there was congestion which prevented the return of the intestine, local depletion was demanded. In this connection he would relate another case that occurred under his notice in the New York Hospital. On the day that the late Dr. Ives was buried, a patient was brought in with strangulated inguinal hernia. As the man was suffering a good deal of pain, and there

appeared to be considerable congestion about the part, he applied some leeches before going out to attend Dr. Ives's funeral, expecting to operate on his return. When he came back in a couple of hours, however, he found that spontaneous reduction had occurred.

On motion of Dr. Howe, the further discussion of the paper was postponed to a special meeting to be held at the call of the Chair; and after attending to some unfinished business the Academy then adjourned.

Correspondence.

THE MONUMENT TO EPHRAIM McDOWELL.

Its Dedication in Danville, Ky., on May 16th.

ORATION BY SAMUEL D. GROSS, M.D., LL.D., D.C.L.,
OXON.

The letters read, speeches made, and other incidents of the occasion.

(Special correspondence of THE MEDICAL RECORD.)

THE Kentucky State Medical Society held its annual session in Danville, commencing on May 13th, and continuing through three days. The meeting was one of the largest the Society has ever held, more than two hundred doctors from the State and elsewhere being in attendance.

The chief event of the meeting was the dedication of the monument to Dr. Ephraim McDowell, the Father of Ovariectomy, who performed his first operation in Danville in 1809. The idea of the monument was conceived by the late Dr. John D. Jackson, of Danville; but it was chiefly by the exertions of Dr. Lewis McMurtry, his successor, and Dr. Turner Anderson, that it was carried out. The subscriptions to the funds were made largely by the medical profession of Kentucky.

The monument is a handsome granite obelisk, thirty feet high, bearing the several inscriptions:

"Ephraim McDowell, M.D., born in Rockbridge County, Va., Nov. 11, 1771; came to Kentucky in 1782; attended the University of Edinburgh in 1793 and 1794; located at Danville in 1795; performed his first ovariectomy in Danville in 1809; died in Danville, June 25, 1830."

"To the memory of Ephraim McDowell, who, in inaugurating a great surgical operation, became a great benefactor to his race."

"Erected by the Kentucky State Medical Society, 1879."

"Honor to whom honor is due."

The monument stands in the old graveyard at Danville, to which the remains of McDowell, now resting in a field on his old homestead, near the town, will soon be brought.

Dr. Washington L. Atlee, of Pennsylvania, had accepted the invitation to deliver the oration upon the occasion of unveiling the monument. Upon his death, Dr. McMurtry, the Chairman of the Committee of Arrangements very fittingly invited and secured Dr. Samuel D. Gross, of Philadelphia, to perform that duty.

The dedicatory exercises were held in the Presbyterian Church of Danville, on the evening of May 14th. The edifice, which is a very large one, was completely filled by the members of the Society, and numerous visitors from the community, which is one of great culture, as well as by visitors from abroad,

attracted by the fame of the orator and the interest of the occasion.

Besides Dr. Todd and other officers of the Society, there were seated on the stage the Governor of Kentucky, James McCreery; J. Stoddard Johnson, the Secretary of State; Dr. Kimball, of Massachusetts; the ovariectomist, Dr. L. P. Blackburn; Dr. D. W. Yandell, Dr. Lewis A. Sayre, the President of the American Medical Association; Dr. Dunlop, Dr. Edward Richardson, Dr. Lewis McMurtry, Dr. R. O. Cowling, Dr. V. P. Gibney, and others.

Dr. McMurtry introduced Dr. Gross as one needing no introduction from a Kentucky audience, and he was received with great enthusiasm.

The delivery of Dr. Gross's oration occupied one hour and a quarter, and was read with great effect by its venerable author. Though the subject was necessarily technical at times, it was received with marked attention by the mixed audience. It is the opinion of professional judges that the McDowell oration is one of Prof. Gross's most masterly efforts, ranking fully with, or surpassing his memoir upon Robley Dunglison, which had been considered among the best of his many contributions in this field of literature. It must hereafter be looked upon as the official record of McDowell's actions and the history of the operation which he introduced. The Kentucky State Medical Society has provided for the immediate publication of a memorial volume of the dedicatory exercises, in which the address will appear in full.

At the close of Dr. Gross's oration, Dr. Lewis A. Sayre, of New York, made a few remarks, in which he said that not only as a private member of the medical fraternity, but as the President of the American Medical Association, he had come to Danville to represent the profession of the United States upon the occasion when a monument to McDowell was to be dedicated. He would not attempt to add to the words of the great orator of the evening, but would simply hope that McDowell's example, and the monument erected to his memory, would stir others to great deeds for the benefit of humanity.

Succeeding Dr. Sayre, Dr. D. W. Yandell read selected letters from a number which had been sent to Dr. McMurtry and himself, in answer to invitations to be present upon the occasion of the memorial exercises. Among these were letters from T. Spencer Wells, Knowlsey Thornton, T. Gaillard Thomas, T. G. Richardson, Theophilus Parvin, Horatio Storer, Thomas Bryant, and Oliver Wendell Holmes.

Dr. R. O. Cowling, of Louisville, had been appointed by the State Medical Society to present to Dr. Gross a memento of McDowell and of the occasion which had brought him to Kentucky.

The object chosen was the knocker which had hung on the door of the great ovariectomist during his residence in Danville. It is in itself a handsome work of art—an antique bronze of very handsome pattern. It has been preserved in the town during the past fifty years as an object of curiosity, and was happily secured for the State Society by the Committee of Arrangements from its owner, Dr. Dunlop, the newly elected President, to be presented to Dr. Gross in the name of the Society on the present occasion.

DR. R. O. COWLING'S ADDRESS.

DR. COWLING said:

Dr. Gross:—The Kentucky State Medical Society thanks you for the beautiful oration you have just delivered upon Ephraim McDowell. Surely hereafter, when history shall recall his deeds, and dwell upon his memory, it shall relate how, when he was fifty years of age,

the greatest of living surgeons in America came upon a pilgrimage of a thousand miles to pronounce at his shrine the noble words you have spoken.

The Society does not wish that you should return to your home without some memento of the occasion which brought you here, and which shall tell you also of the admiration, the respect, and the affection it ever bears for you.

I have been appointed to deliver to you this simple gift, with the trust and belief that it will always pleasantly recall this time and be a token of our feelings towards you. We wished to give you something directly connected with McDowell, and it occurred to us that this little memento of the dead surgeon would be most appropriate. It is only the knocker which hung upon his door, but it carries much meaning with it.

The sweetest memories of our lives are woven about our domestic emblems. The hearthstone around which we have gathered; the chair in which our loved ones have sat; the cup their lips have kissed; the lute their hands have swept—what jewels can replace their value? Do you remember the enchantment that Douglas Jerrold wove about a hat-peg? How at the christening of the child they gave it great gifts of diamonds, and pearls, and laces, and when the fairy godmother came, and they expected that she would eclipse them all with the magnificence of her dowry—how she gave it simply a hat-peg? They wondered what good could come of that. The boy grew to become a man. In wild pursuits his riches were wasted, and at last he came home and hung his hat upon that peg. And while the goodman's hat was hanging there, peace and plenty, and order and affection sprang up in his home, and the hat-peg was, indeed, the talisman of his life.

I wish that the magician's wand were granted me awhile to weave a fitting legend around this door-knocker, which comes from McDowell to you, Dr. Gross. There is much in the emblem. No one better than you knows how good and how great was the man of which it speaks. It will tell of many summons on mercy's mission which did not sound in vain. Ofttimes has it roused to action one whose deeds have filled the world with fame. A sentinel, it stood at the door-way of a happy and an honorable home, whose master, as he had bravely answered its signals to duty here below, so, when the greater summons came, he as trustfully answered that, and laid down a stainless life.

It belongs by right to you, Dr. Gross. This household genius passes most fittingly from the dearest of Kentucky's dead surgeons to the most beloved of her living sons in medicine. She will ever claim you as her son, Dr. Gross, and will look with jealous eye upon those who would wean you from her dear affection.

And as this emblem, which now is given to you, hangs no longer upon a Kentucky door-way—by this token you shall know that all Kentucky door-ways are open at your approach. By the relief your skill has wrought; by the griefs your great heart has healed; by the sunshine you have thrown across her thresholds; by the honor your fame has brought her; by the fountains of your wisdom, at which your loving children within her borders have drunk—the people of Kentucky shall ever open to you their hearts and homes.

The applause which greeted the remarks of the speaker, and the sympathetic attention with which they were received, showed that he had thoroughly interpreted the feelings of the assemblage.

Dr. Gross appeared much affected during the delivery of the address, and at its conclusion, in a most feeling manner, made his reply.

THE REPLY OF DR. GROSS.

I am much overcome, gentlemen of the Kentucky State Medical Society, by this mark of your approbation. I am not the great man your speaker has declared me to

be; but I gratefully appreciate the feelings which have prompted his words.

I claim to be but an earnest follower of surgery, who, during a period which has now extended beyond half a century, has striven, to the best of his ability, to grasp its truths and to extend the beneficence of its offices. I am not to be placed by the side of McDowell for what I may have done in our art; but if this reward be a measure of the appreciation I hold for the good-will of the people in this commonwealth, I may claim it for that.

The years of my life which I passed in Kentucky represent the most important era in my career. They witnessed many of its struggles, and much of the fruition of its hopes. To the warm hearts of the many friends it was my good fortune to secure within these borders, do I owe it that those struggles were cheered and rewards beyond my deserts were secured.

I take this emblem now offered me as the most valued gift of my life. It shall be received into my home as a household-god, environed by all the memories of goodness and greatness to which your speaker has referred, and, above all, recalling this scene. Dying, I shall bequeath it among my most important possessions to the family I may leave, or, in failure of that, to be preserved in the archives of some society.

I thank you again, gentlemen, and I wish I were able to tell you better how much I do thank you.

At the conclusion of Dr. Gross's remarks, the meeting adjourned amidst great cheering, and the members of the Kentucky State Medical Society crowded around Dr. Gross, and, with many an embrace, testified to the warmth of their individual feelings towards him.

RAPID LITHOTRITY WITH EVACUATION.

MY DEAR VAN BUREN:—I have only just seen your interesting communication on "Rapid Lithotritry with Evacuation," in the N. Y. MEDICAL RECORD of March 22, 1879, and I venture to send you direct a brief remark or two thereupon.

First, I observe that you speak of Dr. Keyes's modification of my lithotrite, by which it will do its work without any clogging whatever, and add that "my (Sir H. T.'s) objection that the original Bigelow's instruments were enormous and unwieldy is therefore not tenable." Let me just say, that my objection to the enormous lithotrites of Bigelow remains, of course, as strong as ever, and I am only too pleased to hear that you have recognized the same evil and have remedied it with lighter instruments. We join, therefore,—and I am sure it could not be otherwise—in shunning large unwieldy lithotrites.

My second remark relates to your adoption of some observations in the *Lancet* regarding what the writer calls "abandonment of my old positions;" a matter, after all, of no very great importance. The observation was an editorial one, and designed to be adverse criticism of myself personally, not of my mode of operating. I felt it, therefore, useless on my part to write a rejoinder. But the whole criticism was founded on the writer's overlooking a single circumstance in connection with the subject, which I do not expect you or any one else to discover, without reference to the context. But I desire you, as one of my oldest friends on your side of the Atlantic, to be rightly informed, even on such a matter as this. In the passage from my lectures, quoted by the critic, as recommending that the aspirator should not be too much employed, I was expressly describing *lithotritry without the use of*

an anæsthetic agent; and at the close of this section you will find the following passage, which, no doubt, he did not observe: "If, however, you find it necessary to execute a large crushing, and the patient is, as he then ought to be, unconscious, it is certainly desirable to remove the debris and small fragments, and relieve the patient of the pain and irritation they will produce in passing naturally; and this apparatus is then invaluable for the purpose."*

But I had at that time already commenced to use ether, which was coming again into fashion here, never liking chloroform, and consequently used the aspirator much more freely. And thus I say, in that same edition: "Other means, Clover's apparatus, for example, which is the best of all, may be employed in a good many cases. I use it more than I formerly did, and with advantage."

Lastly, my dear Van Buren, pray forgive my saying that these terms of abandonment of position, change of front and strategical position, etc., adapted as they are to military men, whose sole business is to maintain certain lines they have held forever and must at the peril of their lives maintain, do not accord with the aims of men who "live and learn." Once more let me quote from one of my first lectures a few words which, I think, I need never change, although others may be changed, if I live and work, as I hope to do, some time longer: "You may rely upon it, with regard to any subject whatever, whether politics or religion, or our own proper profession, if we hold the same opinions at forty years of age as we did at twenty—and, perhaps, looking forward, I may say, if we hold the same opinions at sixty as we do at forty, we live to very little purpose. It is an error to look for a life-long 'consistency' in matters of opinion from men who think for themselves, in whatever department their teaching may be. You must expect them to progress, or they will be bad teachers—just as I hope you are progressing now."

By the way, I should like very much to see and try a Keyes' modified lithotrite. I wonder whether he would look me out a good medium specimen, such as he would like me to try. I will gladly be his debtor. Believe me, my dear Van Buren, . . .

HENRY THOMPSON.

P. S.—A new edition of the same lectures is now going through the press, in which these subjects are much more fully treated. I hope to send you the first copy in a week or two.

LONDON, May 1, 1879.

THE DWIGHT INQUEST.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—In your last week's number, under the heading of "The Dwight Inquest," you refer to the opinion of the undersigned, who were his physicians, and use the following language: "The theory of congestive chill was not very strongly supported by the evidence, and only negatively so by the autopsy. Pernicious ague is often, indeed, a boon to those perplexed by obscure and malignant symptoms, as well as a scapegoat for inefficient observation. It is sometimes equally difficult to swear that it has or has not existed, and perhaps on this account it served a tolerable purpose in the present case."

You will permit us most emphatically to repel the

imputation you cast upon us. We have had no occasion to make a "scapegoat" of pernicious ague, nor to resort to any subterfuge whatever in relation to the case of Col. Dwight. He was under our care and treatment for thirty-five days, during which time his disease was observed carefully and anxiously. Malaria, as an essential element in it, was early recognized and the proper treatment resorted to. It consequently could have been no afterthought to attribute his death to the pernicious influence of malarial poison.

Dr. Delafield made no issue with us. He expressed no opinion on his part, nor did he dispute ours. With the carefulness which should characterize all pathological investigations, he simply reported that to his mind there was not evidence of malarial disease; and there he courteously and considerately left it.

If, as you say, "the whole affair reflects anything but brilliancy upon the profession and the performers," we beg leave to deny any agency on our part in producing such a result. There was no diversity of opinion with us who had the case of Col. Dwight in charge, nor are we conscious of a single act or opinion in the matter that would derogate from the standing of the profession in general or of our own. We were compelled to defend our diagnosis and treatment before a coroner's jury, composed entirely of medical men, the coroner also being a regular practising physician, and we are quite confident of our ability to sustain it anywhere.

When the time arrives that it is proper so to do, the profession shall have the case with its interesting points through the columns of some medical journal, and we will quietly abide the good sense and sound judgment of our professional peers.

GEORGE BURR, M.D.,
J. G. ORTON, M.D.,
DAN. S. BURR, M.D.

BINGHAMTON, May 19, 1879.

[We did not intend to cast imputation upon any one, but, from the facts then and up to this time in our possession, we are of the same opinion still.—Ed.]

New Instruments.

A COMBINED GYNÆCOLOGICAL TABLE AND INSTRUMENT CASE.

By FRANK P. FOSTER, M. D.,

PHYSICIAN FOR DISEASES OF WOMEN TO THE OUT-PATIENT DEPARTMENT OF THE NEW YORK HOSPITAL.

For the past two or three years I have used with great satisfaction an examining table, the chief features of which may be described as follows: when not in use it forms a closed case three feet long, two feet wide, and about three feet in height—forming rather a handsome article of furniture, not at all suggestive of the purposes for which it is chiefly meant. The greater portion of it serves to hold instruments and other appliances—one-half of this portion being taken up by a series of drawers, and the other half forming a closet.

The upper part of the table consists of a couch folded together somewhat after the manner of a Lagatelle table. The central section of this couch extends the whole length of the closed case—three feet. To either end of this portion is hinged a lid one foot wide, making the couch, when opened for use, five feet long, furnished with hair cushions covered with

* Clinical Lectures on Diseases of the Urinary Organs. By Sir H. Thompson, etc. Given in 1875-6. Fourth edition. London: Churchill, 1876.

leather. In this state it is a simple horizontal couch, of convenient height and dimensions for examining patients of either sex in the reclining posture. (See Fig. 3.) The patient's head may rest upon a small separate cushion, which cushion, when the table is not in use, is contained in a third lid, which serves to fill up the space between the two hinged lids above re-

ferred to. For an examination in Sims's posture, one end of the cushion upon which the hips rest (the end corresponding to the operator's left hand, as he faces the patient, is raised, so that that portion of the couch slopes towards the right. Partial pronation of the body is thus facilitated, without the unpleasant effects sometimes produced by a table having a lateral pitch

FIG. 1.

ferred to. At the rear of the table is a hinged step, (Fig. 1, A), resting, when in use, on swinging brackets.

For an examination with the patient lying on the back, the central portion of the couch may be raised to any convenient pitch, as shown in Fig. 1. The

throughout its whole length. Moreover, from the hips resting at a higher level than the trunk, a slight lateral bending of the spine is caused, bringing the vagina more nearly parallel with the rays of light which are depended on for illumination—reaching

FIG. 2.

-stirrups, or foot-supports, are simply inserted into sockets in the frame of the couch, so situated that the distance between the feet may be varied according to circumstances. The shape of the stirrups is correctly shown in Fig. 1—incorrectly in Fig. 2.

the room, as they generally do, from a point somewhat higher than the table. In an examination of this sort, the stirrup for the right foot projects from the side of the table—the one for the left foot, diagonally from the corner, as shown in Fig. 2.

For the knee-elbow posture, the patient's knees may rest upon the step, the middle lid, with its cushion, being interposed, as shown in Fig. 3. For the knee-chest posture, the table is arranged in the main as shown in Fig. 1, but the middle lid, with its cushion, is placed at B. The patient's knees rest upon this, and the trunk upon the declivity formed by the central portion of the couch.

that the surgeon must be guided entirely by the sense of touch in his efforts to cut the wire with the common scissors, and under these circumstances even the most careful operator will at times cut the shaft of the suture, as at \times in Fig. 2, instead of the loop at Z, and the succeeding search for the little loop is then very annoying. In one case, while in doubt whether he had the loop or the shaft between the

FIG. 3.

The deep drawer (Fig. 2, A) may be conveniently partitioned into compartments for bottles, jars, cotton wads, a vessel of warm water, etc.; the others are for instruments. From the fact that the end of the couch overhangs the body of the table, these drawers may be opened without obliging the operator to retreat from the patient.

This brief description may be supplemented by viewing the table, which is made by Messrs. Stohlmann, Pfarre & Co.

TENACULUM SCISSORS.

By GEORGE E. ABBOTT, M.D.,

NEW YORK.

A FEW weeks since, while Dr. T. Addis Emmet was removing some sutures from a perineum upon which he had previously operated at this hospital, he spoke of the desirability of an instrument that will cut the

blades of the scissors, the doctor took a tenaculum, introduced it into the loop, drew it forward slightly, and then cut the wire.

It occurred to me that the tenaculum and scissors might be combined, and with one or two suggestions from my friends this idea has been carried into effect in the tenaculum scissors represented below. The instrument, which was made by Tiemann & Co. of this city, has been tested by Dr. Emmet, and found to work very successfully.

A A' represents one handle and blade of the scissors; B, the other handle jointed to A at D. C C' represents the other blade moving upon A A', and attached to it by means of the U clamps G H, but detachable from it for purposes of cleaning. E E E is a "Y joint" connected to the handles A and B, and to the blade C C' at P. By closing the handles A and B the "Y joint" will throw the blade C' forward, cutting upon A'.

While operating, the shaft of the suture may be used

sutures more accurately than can be done with the common scissors.

In certain cases the sutures are so deeply imbedded as a director if necessary. The blade A' is engaged in the loop of the suture, which is then cut in the manner described above. Before cutting, however, the

scissors should be withdrawn slightly, when, if the blade be upon the shaft only, as at \times in Fig. 2, it will slip upward and may be withdrawn entirely; but if it is engaged in the loop it cannot be withdrawn, and the suture may be cut correctly, as at Z in Fig. 2.

This principle might also be used for scissors to operate in deep or narrow cavities, the blades being bent or curved in any desired direction.

WOMAN'S HOSPITAL, N. Y., April 14, 1879.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from May 11 to May 17, 1879.

MCPARLIN, THOMAS A., Major and Surgeon. Relieved from duty in Department of the East, and assigned to duty as Attending Surgeon in New York City. S. O. 111, A. G. O., May 10, 1879.

PAGE, CHARLES, Major and Surgeon. Relieved from duty in Department of the Platte, and assigned to duty as Post Surgeon in Fort Monroe, Va., and to report by letter to Comdg. General, Dept. of the East. S. O. 114, A. G. O., May 14, 1879.

MOORE, JOHN, Major and Surgeon, when relieved by Surgeon Smith to proceed to New York City, and on arrival report by letter to the Surgeon-General. S. O. 114, C. S., A. G. O.

SMITH, J. R., Major and Surgeon, when relieved from duty at Fort Monroe, Va., by Surgeon Page, to report to the Comdg. General, Dept. of Texas, for duty as Medical Director. S. O., 114, C. S., A. G. O.

TOWN, F. L., Major and Surgeon. Having reported in person at these headquarters, pursuant to S. O. 58, C. S., A. G. O., assigned to duty at Fort Walla-Walla, W. T. S. O. 49, Dept. of the Columbia, May 1, 1879.

WOLVERTON, W. D., Major and Surgeon. Relieved from duty in Dept. of Dakota, to proceed to New York City, and on arrival report by letter to Surgeon General. S. O. 114, C. S., A. G. O.

GIBSON, J. R., Major and Surgeon. Relieved from duty in Dept. of the Platte, to proceed to New York City, and on arrival report by letter to the Surgeon-General. S. O. 114, C. S., A. G. O.

CARVALLO, C., Capt. and Asst. Surgeon. Relieved from duty in the Dept. of the Missouri, to proceed to Washington, D. C., and on arrival report by letter to the Surgeon-General. S. O. 114, C. S., A. G. O.

MOFFATT, P., Capt. and Asst. Surgeon. Relieved from duty in Dept. of the East, and assigned to duty in the Dept. of the Columbia. S. O. 114, C. S., A. G. O.

CLEARY, P. J. A., Capt. and Asst. Surgeon. Relieved from duty in the Dept. of the Missouri, to proceed to New York City, report to the Army Medical Board for examination for promotion, and upon its conclusion report by letter to the Surgeon-General. S. O. 114, C. S., A. G. O.

MUNN, C. E., Capt. and Asst. Surgeon. Relieved from duty in Dept. of the Platte, to proceed to Boston, Mass., and on arrival report by letter to the Surgeon-General. S. O. 114, C. S., A. G. O.

DICKSON, J. M., Capt. and Asst. Surgeon. Relieved from duty at Fort Klamath, and assigned to duty at Fort Stevens, Oreg. S. O. 47, Dept. of the Columbia, April 29, 1879.

EWEN, C., Capt. and Asst. Surgeon. Relieved from duty in Dept. of the East, and assigned to duty in Dept. of the Missouri. S. O. 114, C. S., A. G. O.

PAULDINO, H. O., 1st Lieut. and Asst. Surgeon. Relieved from duty in Dept. of Dakota, to proceed to

Washington, D. C., and on arrival report by letter to the Surgeon-General. S. O. 114, C. S., A. G. O.

ADAIR, G. W., 1st Lieut. and Asst. Surgeon. Relieved from duty in Dept. of Texas, to proceed to Utica, Mich., and on arrival report by letter to the Surgeon-General. S. O. 114, C. S., A. G. O.

SEMG, B. G., 1st Lieut. and Asst. Surgeon. Relieved from duty in Dept. of the South, and assigned to duty in the Dept. of the Platte. S. O. 114, C. S., A. G. O.

WILCOX, T. E., 1st Lieut. and Asst. Surgeon, upon expiration of his present leave of absence, to proceed to Vancouver Barracks, W. T., and report to the Comdg. General Dept. of the Columbia for assignment to duty. S. O. 114, C. S., A. G. O.

TURRELL, H. S., 1st Lieut. and Asst. Surgeon. Relieved from duty in Dept. of Texas, to proceed to Boston, Mass., and on arrival report by letter to the Surgeon-General. S. O. 114, C. S., A. G. O.

LA GARDE, L. A., 1st Lieut. and Asst. Surgeon. Relieved from duty in the Dept. of the East, and assigned to duty in the Dept. of the Missouri. S. O. 114, C. S., A. G. O.

DELEGATE TO THE BRITISH MEDICAL ASSOCIATION. — Dr. George M. Beard, of this city, will represent the American Association for the Cure of Inebriates at the next meeting of the British Medical Association to be held in the city of Cork, Ireland, beginning August 5, 1879.

AMERICAN SURGICAL SOCIETY. — At Atlanta, during the meeting of the American Medical Association, steps were taken to organize an American Surgical Society. The movement was initiated by Prof. S. D. Gross, of Philadelphia, and a committee was appointed to report a constitution and by-laws. Dr. Gugas, of Georgia, Chairman; Dr. Watson, of New Jersey, Secretary.

THE THIRTIETH ANNUAL SESSION of the Pennsylvania State Medical Society was held in Chester, Pa., on Wednesday, Thursday, and Friday last. Dr. Andrew Fleming, of Allegheny City, delivered the Address in Medicine; Prof. Eilerslie Wallace, of Philadelphia, the Address in Obstetrics; Dr. C. T. Hunter, of Philadelphia, the Address in Surgery; Dr. R. A. Cleemann, of Philadelphia, the Address in Hygiene; and Dr. James A. Reed, of Dixmont, the Address in Mental Disorders. Committees, specially appointed, reported on "Medical Legislation," on "State Board of Health," on "Female Assistant Superintendents in Female Departments of Insane Asylums," and on "Epileptics who have become Insane." Our next issue will contain a full report of the proceedings in detail.

Original Lectures.

SECONDARY DEGENERATION OF THE SPINAL CORD.—TROPHIC DISEASES OF THE SPINAL CORD.

A CLINICAL LECTURE DELIVERED AT CHARITY HOSPITAL,

By A. McLANE HAMILTON, M.D.,

VISITING PHYSICIAN TO THE HOSPITAL FOR EPILEPTICS AND PARALYTICS.

(Reported for THE MEDICAL RECORD.)

LECTURE II.

GENTLEMEN:—I propose first to-day to present a number of cases which illustrate certain changes consecutive to brain disease, and known as *secondary degeneration of the spinal cord*.

You are doubtless already familiar with certain appearances presented by this class of patients, for disorders of exaggerated motility as the result of hemiplegia are anything but rare. There are several varieties of very striking post-hemiplegic disorder which follow a large effusion or cerebritis, and may occur either as a result of congenital disease or as a subsequent feature of cerebral hemorrhage.

The first patient presented to-day is a baby eleven weeks old, who has a left hemiplegia of intra-uterine origin. It is rare that an opportunity is offered to see a patient at this stage of the disease from which he is suffering in which the trouble is recognized perfectly. You will notice that the limbs upon the left side are powerless, flaccid, and limp, and while he kicks vigorously and gesticulates violently with the right leg and arm, the extremities on the left side remain stationary. It is also noticed that the skin of the affected side is cold, and even at this stage the muscles are found to have undergone a commencing change. A hemiplegia of this kind, as the result of traumatic cerebral hemorrhage, may be produced by pressure incident to forceps delivery, although the skull of the fetus, as we all know, can endure a great amount of pressure without injury to its delicate contents.

But it occasionally happens, as in this case, that a hemorrhage into the meninges occurs, and a condition is developed which resembles in many respects the adult hemiplegia, but the prognosis is very unfavorable. For in many of these cases a form of secondary degeneration is apt to supervene, and the child becomes deformed, distorted by contractures, and almost helpless, as is illustrated in the next case I show you, a girl fifteen years old.

In this patient you will observe a variety of hemiplegic disorder, which might be called post-paralytic chorea, or to the movements of the hands the term athetosis might be applied. In this case the difficulty is congenital, and there has been, probably, a large cerebral hemorrhage, with descending degeneration, which has involved, to a very decided degree, both lateral columns. You will observe that her feet are distorted and present the appearance seen in an aggravated case of talipes varus; that there is a spastic rigidity which cannot be overcome by ordinary force; that both legs as well as the arms, and also the face, are the seat of jactitations which are decidedly increased when she is spoken to or required to perform any voluntary action. When I hold her wrist, you will observe that there are alternate movements

of flexion and extension of the fingers. These movements she is entirely unable to control. The movements of the muscles of the face resemble somewhat those seen in chorea, but are associated with trembling, which is not the case in the latter neurosis. When I tap any of the tendons of the upper or lower extremities there is a marked increase of the tendon reflex. There are, as yet, no sensory disturbances; the functions of the abdominal organs are apparently normal, and her general condition is very good. None of these movements can be said to be essentially choreic, although the disease, doubtless, is very often confounded with that common disorder of early life.

The next patient, a man thirty years old, I present to illustrate a more advanced stage of this condition beginning in early infancy. His deformity is unilateral. You will observe that his entire left side is terribly distorted; that his mouth is drawn to one side; and that his extremities are in a constant state of violent movement. In none of the cases already shown you has there been any muscular atrophy, except that which might arise from the contracted condition of the limb; but there are cases which resemble these in which there is unilateral trouble due to want of development. In this case, E. B., a woman, who has been an inmate of the hospital for twenty years, you will observe a condition which is in striking contrast, in many of its features, with that seen in the other patients, although it might be taken as an example of congenital spastic hemiplegia (*hemiplegia infantilis spastica*). This girl presents a very marked illustration of unilateral atrophy. A careful measurement shows that the arm and hand, as well as the lower extremity, are only about one-half the size of their fellows, while the same side of the trunk is undeveloped and presents a marked difference in size. In this case, undoubtedly, the opposite side of the brain is atrophied, as in the cases reported by Van der Kolk, and more recently by Taylor, and in addition to the bodily deformity there is low mental development and epilepsy, and the convulsions begin in the paralyzed members. This then is one of the kind of cases described by Bourneville as partial epilepsy. In the next patient may be observed a condition which usually appears later in life, and as the result of a cerebral lesion; there is a destructive process which descends through the tracts of white matter across the pyramids, and down into those parts of the lateral columns to which I alluded at my last lecture as the columns of Fleischig, or the crossed pyramidal columns, and though this is an ordinary termination of certain brain lesions of adult life, it resembles very closely the congenital degeneration. Lesions affecting the internal capsule have been found to be those most likely to be followed by descending degeneration of this kind, and as a consequence many of the symptoms previously described are found. The first indication (often overlooked) of such a descending process occurs usually within a very few days or a few weeks after the cerebral hemorrhage, and is preceded by some general symptoms of cerebritis.

Some of the cases are characterized chiefly by marked contractures of the paralyzed members, while in other cases tremor and disorderly movements predominate. The first local signs of the former complication will be pain which shoots down the shoulder and arms of the paralyzed side, while evidences of neuritis are very often discovered by the pain which follows pressure upon the brachial plexus or the median nerve.

Very gradually, but surely, the fingers become fixed, afterward the hand and forearm. In other cases the

elbow is drawn to the side, while in still others the deformity described by Charcot and Strauss as the *contracture-en-flasque*, finally remains. These contractures seem to involve chiefly the upper extremities, but in some cases the degeneration may descend so as to affect the lower as well. As a condition, observed especially in cerebral hemorrhage occurring in young subjects, and as a rare feature of adult hemiplegia, it will be found that there is simply a rigidity more marked at the elbow- and knee-joints, but it is possible by passive motion to flex and to extend the arm and the leg.

With regard to the variety symptomatized by post-paralytic movements, I may say, that such disorders of movement may be exceedingly numerous, partaking either of the tremor of sclerosis, of the jerkings of chorea, or of the continuous athetoid movements described by Gowers. With regard to prevention and treatment of this condition there is not much to be said, and more depends upon the immediate management of the patient who has suffered from cerebral hemorrhage than upon subsequent treatment.

Of course, in spite of all we can do, it is very possible for cerebral softening to take place, arising primarily from inflammation about the clot, especially in portions of the brain where the cerebral blood-supply is limited, such as the region supplied by the middle cerebral artery. In cases in which it is possible to control the occurrence of inflammation about the clot, we can, in most instances, bring our patient through without the development of any secondary changes.

Any increase in the frequency of the pulse and elevation of the temperature should be promptly met with local derivatives and cardiac sedatives. In those cases in which the temperature is high from the beginning, there is reason to fear the existence of extensive softening, and in such we must be prepared for secondary degeneration. If the degeneration does begin, in spite of our precautions, I find that it is unwise to use electricity in any form. I may here state that I have seen post-paralytic conditions which I believe were dependent entirely upon central cerebritis, caused by the injudicious and premature use of electricity.

The actual cautery may be used over nerve-trunks, should there be pain such as has been already alluded to.

I have found it of the greatest benefit to the patient to wrap the limb carefully with cotton-batting, which should in turn be covered with oiled silk. After the contractures have already appeared, but little can be recommended in the way of treatment. Tenotomy is useless unless the deformity greatly affects the comfort of the patient, the flexion of the finger being so great in such instances as to cause the finger-nails to penetrate the palm of the hand.

Electricity is of little avail. Temporary comfort may be given by soaking the limbs ten or fifteen minutes daily in water as warm as the patient can bear without actual suffering, while general hot-baths are recommended. In cases in which the contracture depends more upon spastic tendinous rigidity than upon actual muscular change, this method of treatment offers unusual advantages. I have found that the tremor is best controlled by the use of conium and the avoidance of general excitement.

TROPHIC DISEASE OF THE SPINAL CORD.

The next class of cases to which I wish to invite your attention are those in which the morbid processes are supposed to be confined to the anterior part of the spinal cord, although their pathology is still a question of dispute.

PROGRESSIVE MUSCULAR ATROPHY.

The first patient is one who exhibits a very interesting and rare form of progressive muscular atrophy. In addition to the muscular wasting, which is bilateral, there exists disorder of the vaso-motor nerves upon the right side of the body. From the fact that he speaks English imperfectly, and is somewhat stupid, it has been found impossible to obtain a very clear account of his early symptoms, but we will assume that, according to the rule, the disorder began with wasting of the muscles of the hand and the forearm, and subsequently involved the muscles of the arm and of the back. In this case you will observe that the upper extremities are alone affected.

This disease, which begins with atrophy, followed by paralysis, prefers the upper extremities, while another form of trophic disturbance, known as *poliomyelitis anterior*, or clinically as essential spinal paralysis, as a rule, invades the lower extremities, and the paralysis *precedes* the atrophy.

In progressive muscular atrophy the course of the disease is usually very slow, the muscles of the palm of the hand and the adductors of the thumb undergoing atrophy in the beginning, so that the hand deformity remains, which has been called *main-en-griffe*, or "claw-hand."

This patient, you will observe, presents this deformity, and, in addition, there is decided atrophy of the flexors and extensors of the forearms as well as the biceps. When he flexes his forearm you will observe that what there is left of the biceps is but a small, rounded lump, while the tendon stands out prominently.

You will also notice a peculiar tremulous condition of the healthy muscles, and those just beginning to be involved in the morbid process. This very characteristic tremulousness has been called *fibrillary* or *vernicular* tremor. The latter term has been applied because it describes the appearance presented by the irregular contraction of muscular filaments when the skin is struck, as though worms were crawling beneath the integument.

The muscles of the back will probably become next involved in the wasting process, and in one case recently under my observation the scapulae were so prominent that I could easily place my fists in the deep cavity between them.

It is the rule, in these cases, to discover certain trophic changes affecting the skin and its appendages, so we quite commonly find diseases of the nails, eruptions, and other cutaneous lesions; but this man presents something in addition to these. It has been found that he sweats profusely upon the right side of the body, which, you will observe, is more atrophied than the left, while the left side is quite dry.

By careful experimentation I have found that when ammonia is held to his nose the right eye almost immediately becomes suffused with tears, while the left eye remains almost entirely unaffected.

When salt is placed upon the tip of the tongue an abundant discharge of saliva from the right corner of the mouth occurs almost at once.

Dr. Claddek has painted with cantharidal collodion two spots of the same size upon either side of the chest, and you will observe that upon the normal side only very slight changes have taken place, while upon the right, or affected side, a blister was formed almost immediately, and it has been slow in healing.

The next case which I present is one in which the atrophy is not so pronounced as in the others. The patient has phthisis, which is not an uncommon com-

plication of this and other affections of the spinal cord. The tendency of the morbid process is to extend upward. The larger motor cells in the upper part of the cord, and in the medulla oblongata, are ultimately involved, various disturbances of the lower cranial nerves take place, and the patient finally dies of asphyxia. Sometimes death occurs from glosso-laryngeal paralysis, which by some is supposed to be the same disease process affecting another region of the cord.

The duration of the disease is variable. Some of these patients recover, while in other cases the disease lasts from five to twenty years, the atrophy meanwhile involving fresh groups of muscles with more or less rapidity.

In the private case already referred to, the disease has lasted for two years, and the atrophy has involved nearly all the muscles of the upper part of the body.

In another patient I have recently seen the disease has progressed but very little during the last ten or twelve years.

A combination of symptoms following disease of both the anterior and lateral columns of the cord has been described by Charcot, and for some time the symptoms of primary lateral sclerosis and progressive atrophy were sadly mixed; but if you meet with a patient presenting an early atrophy with preceding loss of power and some rigidity, complicated, perhaps, with tremor and involvement of both upper and lower extremities, the existence of atrophic antero-lateral disease may be suspected.

Diagnosis.—The only other trophic diseases with which this can be confounded are certain forms of spinal paralysis, and in young subjects the disease known as pseudo-hypertrophic paralysis, and occasionally it is closely simulated by lead paralysis.

In the first case shown to-day the atrophy was *preceded* by the paralysis, while in the last case the age of the patient precludes any possibility of error in diagnosis. In lead paralysis the atrophy involves all the muscles of one limb if it reaches the stage in which it can be mistaken for the disease under consideration, and there is usually *anæsthesia*; besides, if you will bear in mind the fact that there are other signs of general plumbic poisoning, I think you will usually be able to make a correct diagnosis.

Treatment.—The only remedy with which I am acquainted, which affords any hope of success in the treatment of this class of cases, is electricity, and I prefer the faradic current, when it is possible to produce contractions. If it is not possible to do this, the galvanic current may be employed.

In certain rare cases, if the extensors are atrophied, I have been in the habit of using the rubber muscle, which gives support to the hand, and in that manner have increased the good effect produced by the battery.

PSEUDO-HYPERTROPHIC MUSCULAR PARALYSIS.

The next patient, a girl 10 years old, is suffering from a disease which is more rare than the preceding, but is one that belongs to the same group. It is the disease known as pseudo-hypertrophic muscular paralysis, first described by Duchenne, and since that time by Continental and American writers; among the latter my friend, Dr. Poore, of New York, who has done much to systematize the labors of others. This child is one of two in the same family, who are affected in this manner; her sister, now at the Randall's Island Hospital, and almost helpless, presents well-marked advanced symptoms of the established disease.

You will observe that she is a well-nourished girl,

and, but for the fact that she cannot stand, which is a recent feature of the case, you would hardly suppose that anything was the matter with her; but when she is supported and attempts to walk, her legs are spread apart, and there is a waddling gait, resembling somewhat the movements of a duck.

When her clothes are removed you will observe a peculiar deformity, which is one of the most striking features of the disease; I allude to the lumbar spinal curve. This extreme condition of lordosis gives the child a pot-bellied appearance, while if a plumb-line is held at the seventh cervical spine and the lead is allowed to rest upon the floor, you will notice a degree of anterior spinal curvature which is more excessive than that presented in any disease with which I am acquainted. You will also notice that while her thighs are smaller than they should be, her nates are full, quite hard, and that the muscles of the calf are also indurated in the same way. When the flabby condition of the muscles of the upper extremities is compared with the affected condition of those of the lower extremities, it will be noticed that a curious change has taken place, and you may attempt to pinch the latter, but it is impossible to take such a fold of tissue between your fingers at this locality as elsewhere.

When her stockings are removed, the skin at first presents a mottled pink color, but after it has been exposed to the air, it becomes blue and dusky. This is an appearance of the skin seen in connection with many other trophic nervous disorders. There is, apparently, no disorder of sensibility, and the functions of the bladder and bowels are normal. These facts point to a normal condition of the parts behind the anterior columns. The thigh muscles have undergone decided atrophy, which is not an unusual feature of pseudo-hypertrophic paralysis, and probably increases the appearance of the deformity which, in reality, does not depend upon actual enlargement of the muscles. The muscles, seemingly, have increased in volume, but in reality they have undergone only a fatty change—a fatty substitution.

This disease is rarely seen after childhood, and this girl's sister, who is 17 years of age, is the oldest case I have ever seen. The development of the disease, in many cases, is unrecognized until the time comes when the child should walk. Unlike the essential paralysis of infants, there is rarely any initial fever or convulsions at the beginning, and the first symptom noticed is a gradual loss of power.

In cases in which death has occurred, croup, pneumonia, and other diseases, some of which seem to have no connection with the paralysis, have produced the fatal termination.

So far as I know, no cures have been effected by any method of treatment; although electricity has been recommended by Duchenne and others.

CHRONIC POLIO-MYELITIS, OR CHRONIC ADULT SPINAL PARALYSIS.

The last patient presented to-day illustrates another form of paralysis and atrophy. In this case there was a gradual loss of power at the beginning; and now, after a period of several years, we find her bedridden and helpless.

The disease from which she is suffering is known as chronic polio-myelitis, or chronic adult spinal paralysis. In adults and in children there may be also an acute form of the disease, beginning with fever and convulsions, in which there is almost sudden paralysis, followed by wasting of the muscles, but unattended by any sensory changes whatever. The acute form of the disease is not uncommon, especially

among infants; but the patient before you gives a history of a much more rare and tedious train of symptoms. She is a woman between forty and fifty years of age, and for several years has been engaged in the hospital as a helper. In her work she was almost constantly exposed to dampness, as she was obliged to wash the floors of the halls of the wards.

At the very commencement of her disease she suffered slightly from pain in the back, not of a serious character, however, and it was supposed to be rheumatism; and from that time there has been a gradually increasing feebleness of her lower extremities. On examination, they appear greatly diminished in size.

The *extensors* of the foot seem to be most prominently involved by the atrophy, so that through slow contracture of the posterior tibial muscles there is a condition of beginning double talipes.

There is loss of electric contractility, while reflex excitability of the soles and the tendon reflex are normal.

Of late there has been some anaesthesia of the lower extremities. This symptom, however, has been present only during a few months.

There seems to be no trouble with the bladder, and though she has had frequent passages from the bowels, I do not consider that she has any paralysis of the sphincter ani.

Within the last year the morbid process seems to have extended upward, for there is now some difficulty in breathing, her respiration becoming disturbed after very slight exertion.

There is no cardiac difficulty, and there seems to be only a very slight action of the chest-walls. There is neither ataxia nor disturbance of co-ordination. There is subjective coldness of the lower extremities, and a certain amount of mottling, such as I have shown you in another case.

Sinkler, who has recently published cases of this form of paralysis, is disposed to think that in some respects it is identical with the ascending paralysis of Dejerine, and from the respiratory disturbances in this case I am inclined to agree with him.

I regret that I have not a case of the acute form of the disease to show you now. There has been but one case of acute adult spinal paralysis in this hospital during the past five or six years, though upon Randall's Island I have some infantile cases, which I will bring before you upon another occasion. This form of trouble is quite common in general practice among children.

In these cases the resulting deformities are confined almost exclusively to the lower extremities, consisting ordinarily of talipes equinus, associated with excessive atrophy.

Treatment.—As in all other forms of atropho-paralytic diseases, our main reliance in treatment must be upon electricity.

I will here give you a word of caution regarding the selection and use of electric currents. We too often find that cases are pronounced hopeless after a distinct muscular contraction has been produced with electricity, when, after all, the observer has defeated his chances of successful observation in regard to the occurrence of subsequent contractions by the use of a too powerful current.

There are many cases of spinal paralysis in which muscular contractions may be produced by a mild current, and in those cases the careless practitioner is apt to smother any latent electric contractility by using too many galvanic cells.

It is not well to be in a hurry, nor to attempt to accomplish too much at first, for a muscle may contract

once under a stimulus, and not immediately respond a second time.

A second excitation may so enfeeble the muscle that the beneficial results from the first application may be entirely neutralized. It is, therefore, well to begin with a minimum galvanic current, produce one or two contractions, and then allow the muscle to rest for a day, when it will be found that still more marked contractions will follow the use of electricity. When the impaired muscles may be easily aroused by the galvanic current, it will be found that the faradic current may be used with benefit, while in the beginning it will be without effect. It is well to avoid giving pain in the use of electricity, for I have often found that painful applications have done more harm than good. By frightening the patient, they also aid in defeating the chances of recovery.

In addition to electricity, cod-liver oil, the syrup of the iodide of iron, and strychnia, may be given with advantage, although in the condition when the muscle is in reality separated from the influence of the cord, no treatment can be so efficient as that of a local character.

Original Communications.

SOME POINTS IN THE TREATMENT OF TYPHOID FEVER.

By SAMUEL PETERS, M.D.,

COHOES, N. Y.

(Read before the Rensselaer County Medical Society, April 15, 1879.)

THE treatment of typhoid fever has been, and is, a subject of much controversy, which is likely to result in good. When we think of the course pursued in its management for so many years after it was first made known as a distinct disease—the exhausting treatment; the ignorance or neglect of ordinary rules of hygiene; and, again, the idea that the disease could be *broken up*, or, at least, *cut short* of its regular course; and this to be accomplished only by the most heroic practice called antiphlogistic, which meant at that time that the system must be torn down in order that it might be built up; when we think of such instruction and such practice, we do not wonder that a salutary reaction followed (a reaction only too limited), and that Dr. Graves, of Dublin, desired the epitaph written on his tombstone, "He fed fevers."

The agony of a patient with fever *then*—parched with thirst, starved with hunger, choked with crude drugs in massive doses; and his comfort *now*, present a striking contrast. But while a patient's chances of recovery now are much better—while it is less dreadful in all respects; yet it is in any view a frightful disease, carrying off, as is estimated in England alone, 20,000 persons annually. The estimate in this proportion for even Europe and America would be appalling, and the question forces itself upon us, Can this number be diminished? We answer emphatically, yes. I believe it is being diminished every year by means of our better understanding of its etiology as well as its treatment. Yet I fear we have not reached that point of success which even our present knowledge will warrant, imperfect as it is, owing to the fact that many are heedless, or, to use a milder term, unthoughtful, not enforcing the means already known; and many, perhaps, omit to avail

themselves of a proper knowledge of the facts that have been worked out.

In considering the question of treatment, we shall assume a few facts without offering much proof:

First. That typhoid fever is self-limited, its course being completed in about 21 to 28 days. On this point I believe all authors essentially agree.

Second. That the tendency is toward asthenia—exhaustion from waste of tissue—too rapid oxidation; the waste exceeding the supply. The *mode* of dying is another consideration, and is secondary and consequent upon this rapid waste, often very complicated. Liebermeister and others attribute the immediate cause of death to the excessive heat, producing either paralysis of the heart or paralysis of the brain. Nevertheless, this excessive heat is the result, certainly, of rapid waste, and these paralyzes are simply among the various modes of dying. A typhoid patient may die from apnœa, from hypostatic congestion of the lungs, or from syncope caused by general exhaustion of the nervous system, affecting the heart, blood-vessels, respiratory muscles, and indeed every organ of the body. To counteract the modes of death is to counteract the tendency, which, as we have said, is asthenia. This doctrine we are safe in assuming, as it is universally admitted, and is as old as Hippocrates.

Third. We assume that the digestive and assimilative powers of a typhoid patient remain intact—weakened probably in some degree, though not materially, for we find such patients are capable of digesting even large quantities of properly selected and properly prepared food. Upon this point there is also very general agreement. I am aware that the Germans, as a rule, have not fully indorsed this belief; that they have been charged with starving their patients, fearing the injurious effects of food. It will therefore be necessary to briefly examine our assumption of the ability of the stomach to perform its functions. Niemeyer admits the justice of this charge against the Germans, and then distinctly affirms his belief that, contrary to this notion, the stomach and lacteals are ready and willing to benefit by a proper supply of good nutriment. Some careful observers contend that even *solid* food is well appropriated. Prof. Samuel D. Turney, of the Starling Medical College, Ohio, as long ago as 1872, announced this very emphatically, and afterward reaffirmed the same opinion in the *London Practitioner* in the latter part of 1877. On the same point we may refer to an article from the editor of the (*London Medical Press and Circular* for March 20, 1878, who very philosophically argues in favor of reviewing our old notions in regard to solid food. Papillaud, of Lisbon, takes the same position. Dr. Edward Warren, of Paris, says he is "convinced that solid food is often a desideratum," *MEDICAL RECORD*, vol. xi., page 47. Other confirming testimony might be adduced, but I will simply quote a few words from a short paper on this subject which I published in the *London Practitioner* for 1878, as indicating my own opinion: "Over and over again I have found that the ingestion of tender meats or bread and milk has exercised a beneficial influence," etc. However it may be with solid food, we are certainly safe in assuming that proper liquid food, at least, is generally well tolerated, digestion and assimilation being very well carried on.

An examination of the opinions of writers on the treatment of typhoid fever, shows that two classes exist. The first class believe in what they call the specific treatment, including principally the systematic use of cold baths, quinine, digitalis, and mercury, which,

from statistics carefully collected, seem to result in the lowest percentage of deaths. This class contains many that are eminent in the profession, including a large number of Germans as well as French, English, and American practitioners of note. The second class adhere to the ordinary or common treatment, though differing somewhat among themselves, as opinions and observations differ; the difference consisting principally in one part advocating the careful, though persevering and bold use of drugs, with the hygienic and supporting aids; the other part seek to eschew to a considerable extent drugs or other very active measures, relying more especially upon hygienic means, together with a quite active support of the body by means of nourishment, a line of treatment very properly called *expectant*.

I wish to say in passing that the definition of the word *expectant* seems to be quite loose, and indeed wrong, as used by Dr. H. C. Wood in his *Materia Medica*, under the head of "Caloric," including within its meaning every treatment used previous to the systematic use of cold baths. The meaning is, "waiting for the efforts of nature." Certainly his use of it is wrong. "Waiting" was surely not a very marked characteristic of most of the old practice.

We will endeavor now, as briefly as possible, to examine these various lines of treatment, divested of prejudice as much as one can be after an experience of nearly thirty-five years in watching the disease and noting interesting points.

For the past few years the journals and other publications have been very well filled with discussions of the various antipyretics, until the question of their value has been quite well decided. The indications and contraindications may not as yet be all fully determined; however, there can be no great difficulty in applying them, with hopes of no inconsiderable amount of good. The extent, however, to which some, armed with the thermometer, are being carried away in the use of these agents, is perhaps to be regretted. They are likely to be used by many too indiscriminately, for while they are powerful agents for good, they are equally powerful for evil. There may be danger of falling into an extreme, as has too often happened in medicine as in other things. The fever thermometer has admittedly become an exalted little instrument, invaluable truly in diagnosis and prognosis, but it should not be made the principal guide in therapeutics. When its rule becomes as rigid as "the laws of the Medes and Persians;" when it declares everything else at our command secondary; when it fosters the belief that *heat* is the only important part of the fever for us to attend to,—we may be giving it too much sway.

The question, to what extent does the excessive heat of the body *per se* injure or react upon it, is not yet fully settled. Some think the parenchymatous degenerations found after death are *not* due solely to the excessive heat. Dr. Grimshaw, of Dublin, denies such an effect. Prof. A. L. Loomis makes this remark in his excellent *Lectures on Fevers*, published in the *MEDICAL RECORD* for 1876: "As yet, there are no facts to prove this assertion, for the same parenchymatous changes are found in the bodies of those who have died of diseases, the course of which was *not* marked by high temperature, and did not extend over a period of more than 48 hours." Dr. Warren, of Paris, late surgeon-general, writes to the Egyptian army that "the heat developed in typhoid fever and the virulence of the disease itself, do not sustain a necessary and invariable relation." Other very strong arguments are adduced by Dr. Warren, and may be

found in the *MEDICAL RECORD*, vol. xi., page 45. Whatever view, however, we may choose to adopt, there is no doubt that the antipyretics are capable of retarding at least the advancement of these degenerations in some mysterious way, and are therefore not to be forgotten, at least in those cases that seem threatening under other modes of treatment.

Very favorable results are shown in the statistics given in Ziemssen's *Cyclopedia*,—the mortality in some of the German hospitals being reduced from about 27 to 11 per cent. Dr. H. C. Wood, in his *Materia Medica*, page 616, has collected the statistics from 41 different reporters on the antipyretic treatment, and I find the average mortality is 10 per cent.—one per cent. less than that named above. I am inclined, however, to attribute a share of this diminished mortality in Liebermeister's report to the omission of his previous proneness, in common with other German practitioners, to the use of powerful drugs; his attention being given particularly to watching the effects of the antipyretics *alone*. However this may be, I cannot avoid expressing the belief, after carefully testing and examining the subject, that the general, almost exclusive use of the antipyretics, which is becoming so fashionable, "will have its day" like many other things, then settle down to a proper medium *between extremes*; in other words, that the thermometer is not the only nor even the best guide to treatment. In substantiation of such a belief, I offer the following reasons:

I. It is not proved that heat is the destroying agent. This point has been already anticipated.

II. The mortality under supporting and expectant treatment compares favorably with the antipyretic. Liebermeister, on page 227, vol. i., of Ziemssen, in summing up the comparison of mortality under antipyretic and previous treatment, makes it, as previously stated, 11 per cent. against 27.3 under the latter. This is certainly a very striking difference, and in itself convincing. Yet a little examination may lead us to rather different conclusions regarding the absolute necessity of antipyretics. It will be observed that this large mortality was under the old active treatment between 1843 and 1864—the treatment of 37 years ago down to 15. Since that time we know there has been much improvement in the management of this disease in Germany as well as in other countries, especially in the matter of more active support as well as in hygienic rules; so that we cannot doubt this high mortality would now be very much less. Again, as the compiler himself admits, the diagnosis was imperfect during that period, all the mild cases of typhoid being then excluded from the reports. This would reduce the mortality also. Liebermeister, however, has since published an article showing that this fact would not materially alter the figures. Nevertheless, the difference between 11 and 27 per cent. argues strongly in favor of a systematic antipyretic course, especially, as before remarked, in those cases or in those epidemics known to be threatening.

But let us now compare the figures resulting from a mild, supporting treatment—figures that appear to be reliable, and that have been collected with considerable care. Aside from my own practice, which has been fortunate, leading me almost imperatively to observe and note what I saw in medical publications, comparing all that I thus met with my own observations, I find a practice corresponding with my own in the main yields like flattering results.

Dr. George Johnson, F.R.S., Prof. of Medicine in King's College—Physician to King's College Hospital (*London Practitioner*, vol. xv., page 108), shows a

mortality under supporting treatment of $4\frac{1}{2}$ per cent. The same authority also gives another report of fifteen cases—no deaths. Dr. Lucien Papillaud, in a paper presented to the Royal Academy of Sciences of Lisbon, 1869 (*Boston Med. Journal*, vol. lxxxi., page 132), shows a mortality of $3\frac{1}{2}$ per cent. under essentially the same practice. Dr. Lazzell (*Transactions of West Virginia, Phila. Med. Reporter*, vol. xxxvii., page 176), under the treatment—to use his own words—of "the less medicine the better," says that a number of the last cases were treated on lime-water and milk, and *all recovered*. Dr. Grimshaw, of the Dublin College of Physicians, "believes that the mortality in the hospitals in which cold water has been tried, is *much higher* than that of the Dublin Hospitals" (*Reporter*, vol. xxxiv., page 196). Dr. Chas. A. Lee reports 4 per cent. in 1859 (*American Journal of the Medical Sciences*, page 335). This was in an epidemic that occurred in Westchester County, New York. Dr. Flamarion "does not see that this method (cold baths), which at first promised so much success, now gives results more favorable than those obtained by Vallex, Bouillaud, Andral, and Louis," and gives his own mortality rate at $1\frac{1}{2}$ per cent. (*Braithwaite*, Part 72, page 18). Under "Negative and Expectant Treatment," in the Lowell Hospital, from 1840 to 1847, the mortality was $4\frac{1}{2}$ per cent. (Barclay on Fevers). The mortality at the Massachusetts General Hospital for 1829 was 4 per cent.; for 1831, 7 per cent.; for 1836 to 1838, 55 cases—*no deaths*. The reports from Pennsylvania Hospital for four years, ending in 1854, show less than 6 per cent.

This is all I have been able to find in my own library, which were more or less the result of expectant and supporting treatment. The average of the eleven reports given is 3.2 per cent. This, it will be seen, is 7.8 per cent. less than that of Liebermeister's under his most skillful antipyretic treatment.

III. The effects of antipyretics cannot be properly watched except in hospitals. It is admitted that this is not a strong objection, because contenders will say very pertinently that this does not weigh against the favorable results of antipyretics. Nevertheless, it is a matter of importance in private practice both in city and country, especially in the latter. The antipyretic treatment requires the closest care and attention, especially in noting its effects upon the heart, blood-vessels, and, indeed, upon the system generally; otherwise, serious injury might result. A physician only can be trusted. The best attendant will surely fail.

IV. The use of cold baths particularly involves a considerable amount of extra trouble as well as expense. This, like the last, is a minor objection; yet all will perceive it has its application, especially in country places and among the poor.

V. The apparent good effects of antipyretics, as observed in *some* of the German hospitals, may not prove equally favorable in other countries, or in particular localities or epidemics. A striking fact upon this point is, that the hospitals of Vienna, after a thorough trial of systematic bathing, have decided against it; the results proving unsatisfactory, mortality averaging as high as 20.8 per cent., according to Dr. H. C. Wood's table. Mortality at Ulm, under same treatment, 19 per cent.; at Rheinlan, 19; at Stettin, 11; at Ostpreussen, 24, where previously it had been, under ordinary treatment, only 10 per cent. Dr. Grimshaw, before named, has used baths, and says "he will never use them again." Parisian physicians, "so far from establishing the value of cold baths as compared with other remedial agents, have really proved that the

mortality is somewhat increased by them," (MED. RECORD, vol. xii., page 128.) Dr. Pepper, of the University Hospital of Pennsylvania, thinks that "cold bathing cannot be regarded as a mode of treatment with propriety."

VI. Relapses, and various other injuries and dangers, are more frequent under the antipyretics. Various writers sustain this point, and some have already been quoted. Relapses are always to be dreaded in typhoid fever. Liebermeister acknowledges their greater frequency, and says: "It appears that the proportion of relapses, and the number of deaths are both actually increased under the use of cold water." The difference, as he states, is 2.4 per cent. in the relapses, and 8 per cent. in mortality. Biermer testifies to the same fact, as does Lindwurm. The cause of this, as supposed by Liebermeister, is "that this treatment in so far interferes with the normal course of the disease as to retard the development, destruction, or expulsion of the poison as a whole; or entirely to prevent these changes in a certain portion of the poison." Most observers believe hemorrhages are more frequent after baths. This, however, is denied by Liebermeister. Dr. Schultze, of the Heidelberg Hospital, an advocate of baths, says "they cause a considerable increase of hemorrhages by 4.3 per cent." Again, he says, "the different forms of delirium and complications are much increased." And again, he says, "neuralgias, and pains in the feet and muscles of the lower extremities appear frequently." Bed-sores and chest affections are, perhaps, less frequent when baths are skillfully used. The percentage is, however, very small.

Hitherto we have spoken more particularly of baths. For quinine, we may remark that in large doses it is about as certain an antipyretic as baths, and while open to some objections, when used in the largest doses, and is therefore rejected by a few, its reputation is very well maintained; Liebermeister prefers it to baths, if but one antipyretic agent is to be used. Undoubtedly a larger number of contraindications will be found than are at present known, and its indications better understood, especially in the pyrexia. Some precautions, however, are to be remembered. Prof. Lindwurm cautions against its use in large doses in *weak heart*. Prof. Binz shows that large doses are capable of producing death by paralyzing the heart; hence the necessity of watching the condition of this organ before and after the administration of antipyretic doses. Niemeyer abandoned large doses. Dr. Peacock of London reports against it, as does Dr. Edward Warren of Paris, Barclay, Hughes Bennett, and others. My own experience is limited, having found the treatment alluded to in this paper generally sufficient. I can say that I have never observed any evil effects from its use, except that it appears to aggravate the diarrhœa. Dr. H. C. Wood and Roberts Bartholow speak distinctly of its irritant action upon morbid states of the intestinal mucous membrane, yet I do not remember to have observed any mention of this in any writings on typhoid fever.

Digitalis is an acknowledged antipyretic, and like the others is not to be given when there is any considerable degree of cardiac weakness. Liebermeister says: "The rule for its application is just the opposite to what it is in disease of the heart. The impending paralysis of the heart is not prevented by the use of this drug, but seems rather to be favored thereby." The temptation to resort to it in *all* cases, as a "heart tonic," renders this caution doubly important. Certainly there is reason to fear that this powerful remedy may sometimes be misapplied in typhoid fever.

VII. The last objection we will name is that antipyretics are not necessary in a large number; perhaps we may say in a *large majority* of cases of typhoid. We know that the disease is self-limited; that it cannot be cut short; that heat is an inevitable symptom; that we are to support early the otherwise rapidly wasting body; that digestion and assimilation are fortunately on the side of the patient. We may therefore lean confidently upon the excellent hygienic rules well known to us, avoiding drugs and all strong agencies as much as possible. I cannot help thinking these are truisms; some of them very old, none of them really new, yet well worthy of our thought and attention, and as we have seen, not wholly devoid of promise.

One point of the first importance in the management of a case of typhoid fever, is the selection of a large, airy, quiet room. If any point in hygiene is important, it is that of perfect quietude. No person should be admitted except the attendant and physician. A few strange faces in the room for only a brief time will very likely insure a restless night, as well as a higher temperature. Even friends and intimate acquaintances should not be admitted, though they promise to remain silent. If my patients have no other luxury, they *can* and *shall* have this one. Grant it, and a careful, quiet attendant, and the thermometer will surely indicate a lower scale. Next, always prepare everything for disinfecting immediately all excretions, and all the soiled clothing before they are removed, to effectually prevent any further spread of infection. All this is advisable, though we may not indorse the full doctrine of contagion. In the meantime carefully seek for the source whence the patient was first infected, and we will often be happily rewarded with success. The source once found, will be a pleasing subject for thought, and *useful* thought, too. Lastly, assure the patient of his ultimate safety; speak to him confidently, count the days for him, encourage him by assuring him that he can have the disease but once, etc., etc.

I am aware that we are not writing for children, but I like to expend words on such a theme; therefore I shall have full pardon.

Cleanliness is, as all know, important. Especially should the teeth be often and thoroughly cleansed from sordes and foul secretions, which would otherwise be left to form a continual fountain of putrid, poisonous matter. This is to be thoroughly done by the attendant, if the patient is unable to do it for himself.

His position should be often changed, to aid in preventing hypostatic congestion of the lungs and other organs. This little manœuvre is unquestionably of great utility—much more than the time it takes to mention it. Even the brain, I believe, sometimes suffers from this hypostatic force of the blood. I further believe the *weight* of the various organs may discomfort and injure them, when the patient is allowed to maintain one position for weeks. The heart certainly cannot afford this.

I desire now to speak of the question of washing the body, so commonly recommended. I do so with great diffidence, because I shall find myself at variance with most—perhaps I should frankly say, *all* authors. However, we will venture it. Do not be constantly scrubbing the skin, either in health or disease, especially in the latter, when the powers of life are going through with a most trying struggle. It costs vitality something to rudely scour the whole surface frequently. If we were once aquatic animals, we

are not now. Even a full bath a few times a day is not as objectionable as this, the disturbance not being half so great. Where the patient desires it, it becomes another thing, and will very likely do good if not repeated too often.

In regard to alimentation, I need scarcely say it is immeasurably important. It is a radical principle in typhoid therapeutics, based upon experience and the combined testimony of the largest number of those most experienced. We would as soon think of saving a man's life without tying or compressing a severed artery, as to think of treating typhoid without diligent support. Rapid waste is steadily and surely going on from beginning to end. Combustion is intense, involving the tissues everywhere. As Niemeyer well says, "No sort of exercise will use up the body so rapidly as a fever does, and most fatal cases of fever are due to insufficient material being furnished for the replacement of that used up." "Food and sustenance," says Aitken, "are the real preventives of delirium, and the best stimulants of the nervous system." Invariably do we see a patient who has been well fed, get up from a typhoid fever but little emaciated. More than this, such ones convalesce more rapidly. There can be no doubt in the propriety of even crowding the patient to take nourishment, especially if he is listless or refuses. I am sure by so doing many a life has been saved.

The kind of food has been a subject for much discussion, but it is now pretty generally settled that *milk* should form the basis. It is at once abundant, cheap, always ready, no cooking process needed, and it contains all the elements of support and nutrition which the system requires; nature's own compound, and like herself *perfect*; adapted to all ages, as well as every stage of the disease. It may be given clear, or, perhaps, preferably with lime-water, and if it produce a fulness at the stomach, failing to digest properly, it may be aided with pepsin, as recommended by Dr. W. H. Thomson, of New York. The quantity should be, if possible, from three to six pints in twenty-four hours. I once had a case, a lady of large frame and plenty of adipose tissue, that drank every day four quarts by measure of clear milk. I was frequently inquired of as to the probability of her recovery. I answered that she *could not die*, because she was able to appropriate so much nourishment. She recovered, of course!

For the diarrhoea there is probably nothing equal to a milk diet, and as a support to the nervous system it can scarcely be surpassed. It must not be forgotten, however, that it fails to agree with all cases; that it requires in some instances to be given in smaller quantities, the deficiency to be made up in other food. Occasionally a case will be found wherein it must be discontinued altogether. Very rarely indeed, however, must this happen. Solid food, as before said, is often agreeable, such as tender meats, stale bread, etc. Grapes and peaches I have always found acceptable, notwithstanding their interdiction by Liebermeister.

Beef-tea, so fashionable the world over, is at best *poor stuff*. It easily ferments in the stomach, and must then surely increase the diarrhoea as well as the typhoid, by filling the intestines with gas (Ziemssen, Johnson, Liebermeister), and further, we know it contains little nourishment. I have generally found eggs objectionable also, especially if taken raw in the form of egg-nog.

Unctions of the whole cutaneous surface, several times a day, with fresh lard or olive-oil, with or without lime-water, are highly useful. Many are aware

of their beneficial influence over the extreme heat of scarlet fever. They are equally valuable in typhoid fever. They reduce the heat quite perceptibly; keep the skin moist, open, and active; sheath the sensitiveness of the cutaneous nerves, and thus promote rest. I find they are highly praised by Dr. Thomson, of the University of New York, who has marked a fall in temperature of from one-half to a full degree. He further believes it relieves the thirst by "restoring the functions of the skin, which enables it to add water to the system when needed, as well as to abstract it when the circulation is too full." He is quite sanguine in the belief of its good effects also in cases of general anasarca when the skin is tense and thus rendered incapable of performing its functions. Furthermore, he thinks these unctions prevent bed-sores (MED. RECORD, vol. x., page 709). Dr. Edward Warren also indorses these views fully.

Drugs are often useful. A discreet physician finds some use for them to subdue, now and then, an excessive diarrhoea, or cough, or active delirium, or other symptom. But many believe, with myself, that in fevers and most other self-limited diseases the old maxim is appropriate, "Throw physic to the dogs."

Antipyretics have their place, as we have tried to show, especially quinine; but remember they are not *always* called for when the thermometer gives an alarm.

Turpentine is a most useful remedy in the later stages. Opium and acids are occasionally called for, etc., etc.

A long list of names could be appended to the above sentiments, but we will close with the excellent words of Dr. Aitken: "It is, above all, necessary to guard against the habit of trying always to be doing something."

PLACENTA PRÆVIA—INDUCTION OF LABOR—AN ILLUSTRATIVE CASE.

By EDWARD L. PARTRIDGE, M.D.,

NEW YORK.

APPROXIMATELY, the mortality in placenta prævia, as indicated in the statistics collected by Sir James Simpson, Dr. William Read, and Dr. Trask, and in the recorded and related experience of many other noted obstetricians, may be stated to be between twenty and thirty-three per cent. as regards mothers; while between fifty and seventy-five per cent. of the children have perished.

The induction of premature labor, as a method by which this large mortality may be diminished, is a practice which has been advised and adopted within a very recent period of time. A no less reliable writer than Dr. T. Gaillard Thomas is responsible for the statement that he believes that, previous to fifteen years ago, "no work, essay, or text-book" advised this method of treatment. Previous to this time, it is true that in many cases premature labor occurred spontaneously, and in other cases the means adopted to control hemorrhage—such as the tampon—had the effect of exciting uterine action; but it remained for Greenhalgh in England, and Thomas in this country, to clearly show that the induction of labor, perhaps not even at the time when a hemorrhage was taking place, but in *any case* in which the *existence of placenta prævia was ascertained*, was the chief factor in the successful treatment.

The principal advantage of this over other methods arises from the fact that the entire labor is under the immediate observation and control of the attendant,

while the danger of a sudden and fatal hemorrhage previous to his arrival, if he decides to wait until the natural termination of pregnancy, is a grave one.

These statements, I think, afford a sufficient reason for relating the following illustrative case:

On April 12, 1879, I was called to see Mrs. S., and obtained from her this history. She had borne six living children, and was now thirty-seven years of age. Her labors had always been characterized by her medical attendants as tedious, but were never complicated. Her last menstruation was from July 6th to 8th, and she was therefore approaching the end of the ninth month. On January 10th she was attacked with pneumonia, and was sick a little more than two weeks. On January 25th, 26th, and 27th she observed a moderate discharge of blood, unattended by pain, which was sufficient to stain her clothing, but was not worthy of being called a hemorrhage. Six weeks ago a similar discharge appeared, which continued three days. Four weeks ago she sustained a severe hemorrhage, and, in a few hours, lost more than eight ounces of blood. Rest in the recumbent posture checked the discharge, though it continued in moderate quantity for three days, during which time there escaped some coagula.

On the morning of April 9th, she took castor-oil, and in the evening of the same day, while having a movement from her bowels, she was seized with a sudden and profuse hemorrhage. This continued to be excessive, and she remained constantly in her bed. Any movement would aggravate the flow. Up to the morning of the 12th inst., during this attack, she thinks she lost more than eight ounces of blood. She passed several clots as large as half an orange, but had felt *no pain* of any kind. Her statements were not exaggerated, as they agreed with those of her husband, and both were persons of intelligence.

When I saw her on the 12th, she exhibited, to some extent, the effects of the loss of blood. The pulse was slightly accelerated, and the face and mucous membranes of the eyelids and lips somewhat blanched, still she "felt well." Local examination revealed the os high in the pelvis. The cervix was very soft and about two inches in length. Two fingers could be passed within it and the structure of the placenta detected in all directions. The discharge of blood at this time was in quantity as if she was menstruating. Fœtal movements were vigorous. During the next few hours nothing of any importance occurred. In the evening Drs. J. Williston Wright and J. H. Fruit-night saw the patient in consultation with me. The latter gentleman had attended the patient in the past, but understanding the requirements of such a case, and living at a considerable distance from her, had kindly referred her to me.

The proposition to induce labor and deliver her at once was accepted by all of us as the best treatment for the case. An enema served to empty the rectum of a large fecal accumulation. A more complete examination revealed the strong pulsations of the fœtal heart at 152, most distinct in the right hypogastrium, but quite perceptible to the left of the median line. The uterine souffle was most marked above the line of the umbilicus toward the patient's right side. Palpation showed the child's head inferiorly and a little to the left of the median line; the breech could be felt to the right, superiorly.

Chloroform was administered and the patient kept partially under its influence. At 9 p.m. the middle-sized Barnes's dilator was inserted, distended, and in ten minutes removed from the vagina into which it had slipped from the os.

The large dilator was introduced and was in position about twenty minutes, when its usefulness ceased, owing to the dilatation of the os, and it was removed. Each dilator served not only to effect expansion of the os, but also to dissect up the placenta for a little distance beyond the margin of the os, so that there ensued no hemorrhage after their removal.

The chloroform was now pushed until complete anesthesia was produced.

It was determined to perform internal version, and I passed my hand into the vagina and cervix and began to rapidly separate the placenta from its uterine attachment. At first this was done in all directions, with the hope that at some point its margin would be reached at no great distance from the os, but not finding the placental border within easy reach, and profuse hemorrhage commencing, I chose to advance in the direction (toward the mother's left) which, owing to the child's position in utero, offered the most ready access to the feet. Passing my hand between the membranes and the uterus, until near the fundus, the left foot was easily distinguished and seized through the membranes. Version was readily accomplished, the arms brought down, and delivery completed at 9.45 p.m. The placenta came with the child. There was very little liquor amnii. The length of time from the introduction of the first dilator until completion of labor was forty-five minutes, and the time from the introduction of the hand into the vagina until the termination of delivery, less than ten minutes. About four ounces of blood was lost.

The child weighed eight pounds, and had a pulse of about eighty at birth. Within a minute respiration was established with natural heart's action. During the process of dilatation about eight slight uterine contractions took place, the uterus straightening up and becoming hard. During the extraction of the child, the uterus acted forcibly, and, after delivery, never for a moment showed any disposition to relax. Ergot was administered subsequently. There was no condition of shock resulting from the rapid delivery.

An hour and a half later the patient was asleep with a pulse of eighty. Convalescence was normal in every respect and the child was strong and active.

The placenta—which was centrally situated with almost mathematical accuracy—was of large size and nearly circular. Its greatest diameter was ten, and its shortest eight and half inches. In its centre, at the point of implantation over the os, there was an accumulation of white fibrous tissue. The umbilical cord measured fifteen inches.

The oft-quoted statement made by Nagele concerning placenta prævia, that "there is no error in nature to be compared with this, for the very action which she uses to bring the child into the world is that by which she destroys both it and the mother," will always remain full of meaning. I cannot but feel, however, that when the induction of labor is recognized and practised as the *important* element in the treatment of this complication, statistics will place "unavoidable" hemorrhage in a very different position from the formidable one which it occupies in the literature of the past and in the mind of the practitioner.

It is as important to decide upon the proper *time*, as upon the best means to effect delivery.

The arguments in favor of this method of treatment, which have been offered by Greenhalgh, Thomas, and Parvin, cover the entire ground, and there seems to be little to add now except statistics to confirm them. Owing to the infrequent occurrence of placenta

prævia, an accumulation of cases from which to draw deductions can come only in many years.

It is certainly the duty of practitioners to report faithfully both successful and unsuccessful cases in which induction of labor is employed, until there can be no doubt in any mind concerning the utility of the operation in this class of cases, which, in the past, has excited much anxious attention from general practitioners and renowned obstetricians.

Reports of Hospitals.

BELLEVUE HOSPITAL.

NOTES OF PRACTICE AND PECULIARITIES OF TREATMENT.

INTERESTING CASE WITH REFERENCE TO DIAGNOSIS—JAUNDICE—MARKED FEBRILE MOVEMENT—DIMINUTION IN THE SIZE OF THE LIVER—DELIRIUM-DUODENITIS—RECOVERY.

THE following case was especially interesting with reference to diagnosis and severity of symptoms: A female patient, a native of Ireland, aged 33 years, a widow, and a domestic, was admitted to the hospital on the 13th of January. Nothing definite could be obtained with reference to her previous history. At the time of admission she had a well-marked febrile movement, the temperature being $105\frac{1}{4}^{\circ}$ F. At the same time she was very deeply jaundiced. Physical examination gave negative results, except with reference to the liver and spleen, both of which were somewhat enlarged. In addition, there were cerebral symptoms; the woman was mildly delirious. The tongue was coated, was brown and dry, and except for the jaundice the patient presented very much the appearance of one suffering from typhoid fever.

On the night of January 14th the delirium became so violent that it was necessary to remove the patient from the ward to one of the cells.

On the 15th of January the patient was again rational and was transferred to the ward. The temperature during this time continued high.

On the 16th of January physical examination was made, and it was found that the liver, instead of being enlarged, was diminished in size.

On the 17th of January her temperature was 103° F., and she was again delirious.

On the 18th of January her temperature was 102° F., the tongue had commenced to clean and was moister, the jaundice had diminished, her mental condition had improved, but the liver still remained small.

On the 19th of January her temperature in the morning was $99\frac{1}{2}^{\circ}$ F., and in the evening 100° F., and she was perfectly rational.

On the 20th of January her morning temperature was 99° F.; evening temperature $99\frac{1}{2}^{\circ}$ F., and she was feeling nearly well.

When first admitted the general condition of the patient was such as to indicate a probable fatal termination of the case, and such prognosis was made during the first two or three days of her sickness. The disease naturally suggested was acute yellow atrophy of the liver. For, soon after admission, there was rapid and marked diminution in the size of the liver, and the jaundice and the cerebral symptoms were well-marked. Against that diagnosis was the fact that there had been neither gastric nor intestinal disturbance. It was remarked that in all the cases of

acute yellow atrophy of the liver which had been observed there had been some disorder of the stomach and bowels, and notwithstanding the jaundice, the high temperature, and the cerebral symptoms, the marked diminution in the area of hepatic dulness, the visiting physician was not willing to say that the patient was suffering from acute yellow atrophy of the liver.

The progress of the case, it was thought, made the diagnosis quite clear, and it was regarded as one of *duodenitis*.

The symptoms were much more severe than those developed in ordinary attacks of duodenitis or gastroduodenitis, but in that respect it was thought that it might safely be regarded simply as an exception to the general rule. For, occasionally cases of apparent duodenitis at least were seen, which gave such a history as the woman before us.

It was farther remarked that if there was good reason to suppose the patient had a fatty liver, it would make the explanation of the case much easier. For, when duodenitis was developed in connection with fatty liver, the symptoms were much more marked, especially the cerebral symptoms. But the liver was of small size, so small that another condition was suggested—namely—*cirrhosis*.

In most women, dressed according to common custom, the free border of the liver is below the free border of the ribs, but in the patient before us the free border of the liver was above the free border of the ribs.

It was thought to be quite possible that the patient was suffering from *cirrhosis* of the liver, which possibly might explain why the symptoms of duodenitis had been so much more severe than in ordinary cases.

The experience was such as the visiting physician had had before, and had led him to the conclusion that it was well not to be in haste with reference to making a diagnosis of acute yellow atrophy of the liver. The treatment was almost nothing.

Quinine was administered when the temperature was the highest, the patient was nourished chiefly with milk, and the disease was allowed to run its course. The case was regarded as one which served well to illustrate how severe the symptoms of duodenitis might be.

Progress of Medical Science.

CHAULMOOGRA OIL IN PHTHISIS.—The value of chaulmoogra oil has been tested by I. Burney Yeo, M.D., in nine cases of phthisis, and the results of his investigations published in the April number of the *Practitioner*. The oil has a nauseous odor and taste, and is solid when cold, rendering it necessary to mix it, after warming, with some diluent, as almond oil. Of the nine cases, three are dead; one passed from observation, after taking the oil for a fortnight, without any improvement; one found it impossible to continue it on account of the gastric disturbance it produced; one appeared to get decidedly worse during the administration of the oil, became very feverish, his temperature rising to 104° , then, on the discontinuance of the oil and the substitution of the hypophosphite of lime and cod-liver oil, he mended considerably; one, after taking the oil for two months, was no better, and was allowed to discontinue it, as he complained that it made him sick; one discontinued his attendance after the first fortnight and sent

word that he was "not so well;" and one improved considerably. These trials are not claimed to be conclusive, but they certainly are not very encouraging. It is proposed to give it one or two more trials in the form of *parles*, and in as favorable and early cases as come within observation.

SULPHUR AS A TOPICAL APPLICATION IN DIPHTHERIA.—Mr. Stuart, of Dunse, N. B., used sulphur for destroying diphtheritic membranes on the tonsils with sufficient success to induce him to report the case, hoping that others may be tempted to test the value of the remedy. The sulphur was applied every hour by means of a quill, and the membrane on the right side had disappeared by the next day; on the left side no trace of it appeared on the third day. The membrane first became blackened, and then detached; but Mr. Stuart does not offer an explanation of the *mobus operuili*. In spite of the rapid disappearance of the membrane, the patient suffered subsequently from a slight attack of paralysis of the larynx and pharynx. Shortly afterward his elder brother became affected with the disease, but made a good recovery under maternal treatment with sulphur. Another case has since been treated successfully in this manner by Mr. Stuart, with the exception that swabbing the throat with sulphur and water took the place of blowing the powder on.—*The Practitioner*, April, 1879.

ANIMAL HEAT.—The source of animal heat has always been an interesting question to physiologists and one difficult of satisfactory elucidation by experiments. Nevertheless, Dr. A. Flint, Jr., thinks he is justified in drawing the following conclusions from his own observations and those of others:

1. It is probable, and indeed almost certain, that nearly all the animal heat is produced by oxidation, in the body, of certain elements, which are chiefly nitrogen, carbon, and hydrogen.

2. It is probable that this oxidation does not take place entirely in the blood, but that its seat is in the various tissues, and that it is connected with the general processes of nutrition and disassimilation. Heat is thus evolved, and the final products of the chemical actions involved are mainly urea, carbonic acid, and water. It must be remembered, however, that the oxidation is not necessarily a process identical with combustion out of the body, but that it is probably connected with a series of intricate molecular changes, which cease with the life of the tissues, and of which we can only recognize the final results, viz., calorification and certain chemical products.

3. Recognizing the products urea, carbonic acid, and water as representing probably the evolution of a certain amount of heat, we cannot account for the heat actually produced in the body by the amount represented by the urea and carbonic acid discharged. If we admit that hydrogen is oxidized in the body, resulting in the evolution of heat and the production of water, this will enable us to account for all the heat actually manifested as heat, leaving an excess which may be converted into force.

4. My experiments show pretty clearly that when no food is taken, and when, food being taken, muscular work is performed, so that there is loss of body-weight, water is actually produced in the body. This, and this only, enables us to account for all the heat evolved under these conditions. There is no reason to suppose that the processes involved in the production of heat are radically changed in their character when enough food and water are taken to maintain a uniform body-weight.

5. Animal heat is produced mainly by the waste of

the hydrogen, carbon, and nitrogen of the tissues, the waste of these elements being supplied by the food. Probably the oxidation of carbon and hydrogen is a more important factor in calorification than the oxidation of nitrogen; at least, it is certain that the heat-value of the oxidation of carbon and hydrogen is greater than that of the oxidation of nitrogen, and the heat thus produced is very much greater. Of the two elements, carbon and hydrogen, the oxidation of which produces animal heat, the heat-value of the hydrogen is by far the greater.

6. It is probable that there is always a certain amount of oxidation of hydrogen in the body, and that this is necessary to maintain the animal temperature; and it is almost certain that this occurs during prolonged absence from food, and when the production of heat is much increased by violent and protracted muscular exercise. It may also be that there is an active and unusual oxidation of hydrogen, as well as of carbon in fevers.—*American Journal of Medical Sciences*, April, 1879.

UNUNITED FRACTURE OF THE HUMERUS.—A case of ununited fracture of the humerus, which had resisted all efforts to make it unite, was successfully treated by Dr. Le Moyne, Pittsburg, Pa., by double splice and clamp. From the lower fragment a piece was removed, leaving a V-shaped depression, into which was fitted the wedge-shaped extremity of the upper fragment. A clamp of steel wire, bent at right angles a short distance from either extremity, was now fitted to the bone, a hole being drilled in either fragment for the bent extremity of the clamp. Apposition was perfect; splints were applied, and the patient kept at rest. The next day, however, the clamp had shifted, and some displacement ensued. Wires were now passed around the bone, so as to secure the clamp to both fragments, splints re-applied, and the wound dressed with oakum and balsam of Peru. The operation was performed on the 23d of October, fifteen months after the receipt of the original injury. On November 26th the dressings were completely removed for the first time, and some union found; by December 9th the union was firm and complete. About December 20th, an attempt was made to remove the wires and clamp; but they were so firmly imbedded in the provisional tissue, and the wound appeared so healthy, that the wires were cut short and they were left in position. When last seen, the wound had almost closed; the mobility of the elbow-joint was somewhat impaired, but improving.—*The American Journal of Medical Sciences*, April, 1879.

DUBOISIA AS A MYDRIATIC.—The local effects of duboisia myoporoides, when applied to the eye, are similar to those of atropia; but they are more promptly produced, and disappear more rapidly. Its greater tendency to produce constitutional disturbance, however, should cause it to be carefully used. Nearly every patient into whose eyes a four-grain solution had been dropped complained of dizziness within a short time after its instillation, usually noted after rising from their chair. They do not, however, complain so much of dry throat as those treated by atropia. Where persistent use of atropia has failed to tear loose posterior synechie, but little effect has followed the employment of duboisia. On the other hand, it gave much satisfaction in two cases where atropia called forth marked conjunctivitis. One was a severe iritis, the other a case of cataract, where, owing to capsulitis following extraction, it was desirable to maintain dilatation of the pupil.—Wm. F. Norriss, M.D.: *The American Journal of Medical Sciences*.

DUTY ON CINCHONA ALKALOIDS.

For some time an effort has been made to secure the passage of a bill by Congress which shall remove the duty from the cinchona alkaloids. The effort thus far has for some reason failed. It being a question in which the medical profession is directly interested, the nominal influence of that great body has from time to time been sought in favor of the enactment of such a law. It is, we believe, the prevailing opinion among medical men that the duty on these articles should be removed; and the representative body of the medical profession in this country, the American Medical Association, has at various annual meetings declared itself in favor of such a measure, perhaps without knowing exactly why, or how, the crockery in this china-shop should be broken. At the last meeting of the American Medical Association, held in the present month at Atlanta, a delegate from Philadelphia presented a bit of fine ware in the shape of a memorial, or petition, or communication from his county medical society, asking the Association to reverse its former action, and declare itself in favor of allowing the law to remain unchanged. The communication was immediately tabled; and not only that, but the gentleman upon whose motion it was laid upon the table, at once moved and secured an unanimous affirmative vote of this delegated body, containing representatives of the profession from a large number of the United States, upon a resolution asking Congress to remove the duty upon all alkaloids of cinchona. This action on the part of the profession had its effect, for upon the following day, a monopoly, represented by the three largest manufacturing companies in this country, appeared before the Association wearing the old threadbare suit in the form of a communication addressed to the Chairman of the Committee of Arrangements, stating that if the duty

on quinine was removed, they could no longer continue its manufacture. That communication was also laid upon the table, thus showing that the profession had little fear its wants in that direction would not be supplied. Neither the profession nor the people need fear that the alkaloids of cinchona cannot be obtained, should the duty be removed at once and these firms cease manufacturing them. But they would not stop their work. It is doubtless true that the cinchona alkaloid can be as well and as cheaply made here as in any other country; that the duty simply increases the profits; and that no makers with established apparatus and processes will stop if the duty is removed. But suppose they do stop, it will not harm the therapeutic interests, because the cinchona-barks they use would remain in Europe, or go directly there, and the same quantity of alkaloid salts would at once be accessible at lower prices. This is true, simply because the duty now enables manufacturers here to pay higher for barks than they would bring in Europe, thus rendering our makers injurious competitors with the cheap makers in Europe, while the higher prices paid here for barks are transferred to the cost of the consumer in the product. Again, if the makers in this country should stop their machinery, the cinchona market of the world would lose the competition of a powerful monopoly supported by a direct tax on the consumer, and all Europe would get barks cheaper, thus enabling it to produce alkaloids at lower prices, and in the same aggregate quantities. All the cinchona-barks produced and producible at the present low prices are made into alkaloid salts, and probably will be, and the salts are all consumed, and it is a matter of small moment to this country where the salts are made, so they are made. It is, however, of very great importance that they should be had cheaply; and if our makers should stop now, with the duty on, and not deal in either the barks or the salts, the latter would probably be sold cheaper in this market than they now are. As an evidence that this is true, our makers have for a long time been large importers of these salts, and have themselves paid the duties, with a fair presumption that they made money on their importations, as well as a much greater profit on what they manufactured. There are thousands of consumers in this country who suffer from a direct tax imposed upon them by a wealthy monopoly at home, aided by an act of Congress that fixed an iniquitous discriminating duty of 10 per cent. on articles coming via Europe from the east of Cape of Good Hope. We believe that Congress cannot do more to relieve suffering humanity in the United States than would be realized from an immediate removal of all duty from cinchona-barks and their alkaloids. The resistance from monopolies will be great, but the medical profession and the people will sustain their representatives in such a movement.

THE INCREASE OF MALARIA IN NEW YORK CITY.

FOR some time there has existed an impression that malaria is rather increasing than diminishing in New York, and this has been remarked especially during the past winter. Statistics, so far as they go, tend to corroborate this idea. Thus the total number of deaths from malarial diseases, including also typho-malarial and simple continued fevers, was in the six months, including the winter of 1874-'75, only 118. In the corresponding six months of succeeding years this number gradually increased to 125, 132, and 139, while in the six months ending with March, 1879, the number was 178. The number of deaths in the other half of the same years shows a similar gradual rise.

Now, as the mortality from malarial poisoning is extremely small, it is obvious that under ordinary conditions even a slight rise in the death-rate would indicate a very large increase in the number of cases mildly affected by the disease. Without claiming too great value then for the figures given, we believe it a fair inference that malarial diseases have been and still are increasing in this city. If it be so, the fact warrants some attention. This, indeed, it has already received in some quarters, and speculations and inquiries as to the cause are appearing in print.

It is asserted that there have not been any sufficiently marked meteorological conditions to account for the increase of the disease, also that this increase cannot be laid to upturning of the ground, or to old water-courses, or defective plumbing; for, if anything, there has been improvement in all these things. As a last resort, the theory is broached that the malarial germs are brought to the city by croton-water. The capacity of the lakes from which this water comes has been severely tested of late. They have been drained so low as to lay bare their banks to a considerable extent, and have thus increased the amount of malaria in their vicinity. The idea, therefore, that the poison is conveyed to us through the pipes appears at first to have some plausibility. We are by no means inclined to adopt it, however. It has, in the first place, never been proven that malarial poison can enter the system by drinking-water, it being more likely, in the few cases where this has appeared to be the case, that the bad water was only an exciting cause. To mention no other argument, however, the fact that the mortality from malaria is not notably increased in the summer months, when alone the poison can breed, is marked evidence against the theory.

The truth is that the ways of the malarial germ are often erratic and inexplicable. Although warmth, moisture, and decaying vegetable matter are generally the factors in producing it, these are often insufficient, and other and inscrutable elements must be assumed as exciting or preventing its development. There seems to be such an element in the present increase of the disease in this city.

THE PLAGUE.

THE name plague has been applied to a number of malignant and rapidly-extending epidemics, between twenty and thirty of which have been recorded as occurring. The bubo-plague, the form of the disease which has recently visited Russia, is a product especially of the present era, and first occurred with greatest severity in the sixth century. The plague in general, however, according to Dr. D. N. Kinsman, who has given an excellent account of it in the *Ohio Medical Recorder*, has occurred in three different forms during the world's history.

In the first form the poison affects the nervous system especially. The patient is suddenly and violently prostrated, and either rapidly succumbs or recovers.

The second form is the one that attacked Athens and Persia, B.C. 540. The disease was graphically described by Thucydides as follows: "There was headache, fiery redness of the eyes; the tongue and throat were blood-red; the breathing was difficult and of noisome odor; there was sneezing and hoarseness, spitting of blood, vomiting, fluxes from the bowels, and hiccough. The body was reddish, with livid pustules and sores; there was a sensation of great internal heat. The patients could not remain covered with clothing; they longed for nothing so much as to be plunged into cold water, and many, from not being properly attended, plunged into wells and perished. There was great restlessness, so the patient could not sleep. In spite of this terrible condition, there was no visible wasting of the body. The malady at times beginning in the head, shot down into the fingers and toes, and even the private parts, by the losing of which they escaped with their lives. Neither animals nor birds preyed upon the bodies of the dead, and those which tasted died. Some died for want of care, and what was a relief to one was prejudicial to another. Differences of strength or weakness were all swept away by the pestilence. Neither prescription nor diet protected. If fear held them from going near one another, they died for want of help; and if they ventured, they were gone."

The third form, to which we have referred, is attended with intense fever, buboes, and gangrenous sloughs, and has been previously described in this journal. It has appeared as a severe epidemic only four times.

Assuming a certain amount of pathological identity between these forms, the affection can claim no inconsiderable part in the world's history. It has rarely appeared without slaying its thousands, or even millions. It destroyed the hosts of Assyria; the immortal Galen discreetly fled before it; if we may believe historians, it hastened the disruption of the Roman Empire, and was a potent factor in the intellectual and religious changes of the fourteenth century. That it has devastated vast tracts of land, humiliated kings, incited religious as well as medical fana-

ticism, and then destroyed the fanatics, is sufficiently well known. The plague which appeared in the fourteenth century caused the death of 100,000,000 people, its greatest virulence extending over only three years. Those could not have been jovial times. In past years, too, to add to the terrors, the epidemics were almost always accompanied with remarkable terrestrial phenomena: terrific storms, swarms of locusts, earthquakes, and volcanic eruptions.

Passing from its history, we find the cause of the disease to be a specific contagium, which may originate *de novo*, may be transported by fomites, and be multiplied in the body. It has always been thought to have the peculiarity of being destroyed by extremes of heat or cold; and, as a general rule, this is true.

It can be inoculated, but one attack does not protect from another. When the disease has once appeared, there are but two effective measures that can be taken against it. One is fire, and the other an absolute, or "shot-gun," quarantine. It is one of the few advantages of a despotic government that under it such a quarantine can be enforced. It appears that freemen, however, prefer an epidemic to infringement on their constitutional rights.

But though, when the disease has once appeared, we have no sure prophylactic except isolation, and no certain disinfectant except fire, the habits of life have so changed among civilized nations that the plague which springs from filth and grows upon the distress it causes can never again appear extensively among us. With obedience to the laws of hygiene as a prophylactic, and State medicine as a therapeutic measure, the plague which could once hasten the fall of an empire is now less alarming than the measles. This is surely an indication that we have advanced.

Reports of Societies.

AMERICAN MEDICAL ASSOCIATION.

THIRTIETH ANNUAL MEETING,

Held in the City of Atlanta, Ga., May 6, 7, 8, and 9, 1879.

REPORT OF SECTIONS.

(Continued from p. 497.)

SECTION ON SURGERY AND ANATOMY.

DR. MOSES GUNN, of Chicago, Ill., Chairman; DR. J. R. WEIST, of Richmond, Ind., Secretary.

TUESDAY, MAY 6.—FIRST DAY.

The Section was called to order at 3 P.M. by the Chairman.

The Chairman appointed as a sub-committee, to which all papers read before the Section should be referred, Drs. W. T. Briggs, of Nashville, Tenn.; W. W. Dawson, of Cincinnati, Ohio; and W. F. Westmoreland, of Georgia.

ON DEFORMITIES OF THE FACE AND HANDS OCCASIONED BY CICATRICAL CONTRACTION FOLLOWING A BURN.

DR. A. C. POST, of New York, read a paper upon the above subject, with report of cases successfully treated. The paper was illustrated by means of casts and photographs, and showed one of the great advancements made in surgery. The paper was discussed by Drs. I. N. Quimby, of Jersey City, N. J.; W. T. Briggs, of Nashville, Tenn.; and W. W. Dawson, of Cincinnati, Ohio.

DR. H. O. MARCY, of Massachusetts, then read a paper on

ASPIRATION OF THE KNEE-JOINT.

It contained an account of 68 cases and 118 aspirations. The quantity of fluid removed at each aspiration varied from half an ounce to eight ounces, and was serous, sero-purulent, and sero-sanguinolent. Death occurred in only one case. The best results were derived in acute inflammatory traumatic cases. The operation should be performed early; the joint should be reaspirated as often as fluid accumulated, and followed with an elastic bandage, fixation, and rest.

DR. WM. A. BYRD, of Quincy, Ill., referred to a case in which he had successfully aspirated the knee-joint.

DR. A. C. POST, of New York City, referred to a modified process of aspiration in the treatment of inflammation of the knee-joint. It consisted in drawing off the fluid through an aspirator needle, and then distending the cavity through the same needle with a solution of carbolic acid of the strength of 1 to 30. It was upon the principle of hyperdistention, according to Callender, and Dr. Post was disposed to regard it as an important modification.

—, a delegate, referred to the use of Dr. Martin's elastic bandage after aspiration. So far as his experience went, the results obtained had agreed with those reported by Dr. Martin, and had been very satisfactory. In simple cases of dropsy of the knee-joint, where he had aspirated, and then applied the bandage, there had been no return of the fluid. Of course as much benefit in cases in which the fluid was purulent could not be expected.

DR. S. D. GROSS, of Philadelphia, remarked that he had employed aspiration a few times, not only in the treatment of accumulations of fluid in the knee-joint, but also in other joints, and it seemed to him that aspiration should be regarded simply as an auxiliary measure. In all cases, proper attention should be paid to the general condition of the constitution of the patient; and to the aspiration might be added a variety of means which would tend to bring about a condition that could not be established by aspiration alone. To the aspiration, counter-irritation, elastic compression, etc., could be added, with benefit.

DR. I. N. QUIMBY, of New Jersey, preferred to resort to other means than aspiration in cases in which there was only a small accumulation of fluid in the joint.

DR. MARCY, in closing the discussion, remarked that he heartily indorsed the remarks made by Dr. Gross; but the time allotted for his paper did not permit him to enter upon the general consideration of the subject.

DR. E. B. TURNIPSEED, of Columbia, S. C., then exhibited a *new surgical needle, curved, and spring-clamp at the point; also a new apparatus for treating fracture of the clavicle, with cases; and also described a new method of reducing dislocation of the elbow-joint, with cases.*

The new apparatus for treating fracture of the clavi-

cle consisted in broad leathern collars encircling the shoulders, and united behind by straps from the upper portion of the band, and in front by straps from the lower portion of the collars.

The new method of reducing dislocation of the elbow-joint consisted in standing behind the patient, grasping the arm just above the elbow with one hand with the thumb upon the olecranon process, grasping the wrist with the other hand, and, while extension and counter-extension was being made, to suddenly extend the forearm, and at the same time make pressure upon the olecranon with the thumb.

Dr. S. D. GROSS, of Philadelphia, remarked that there was nothing more easy than reduction of a recent dislocation of the elbow-joint. The plan suggested by Dr. Turnipseed was substantially that recommended by Dr. Waterman, of Massachusetts, several years ago.

Dr. J. S. DODGE, of Bristol, Ind., remarked that Dr. Turnipseed's method was the same as that taught by Dr. J. W. Greene at the University of Michigan.

Dr. J. C. HUGHES, of Keokuk, Iowa, thought the method of treating fracture of the clavicle suggested by Dr. Turnipseed was no better than several appliances already in the hands of the profession. It was, perhaps, very convenient, but he failed to see its special value. Again, with regard to the suggestion made with reference to reduction of dislocation of the elbow-joint, he thought it did not possess the common sense that did the method by lifting the coronoid process out of the olecranon fossa.

Dr. L. A. SAYRE, of New York, thought if the front strap was removed that Dr. Turnipseed's apparatus would be improved. It would then be very much like the old-fashioned figure-of-eight bandage, and no better.

Dr. W. W. DAWSON, of Cincinnati, O., remarked that no apparatus had ever been devised which could keep the shoulder *outward*, except by making a lever of the arm, which it was impossible to do practically because of the pressure produced upon the vessels and the nerves. He thought the action of Dr. Turnipseed's apparatus was to bring the points of the shoulders nearer to each other, and therefore necessarily increased the shortening.

Dr. A. C. POST, of New York, thought that the apparatus did not possess any special advantages.

Dr. GLENN, of Nashville, Tenn., referred to an operation performed by the late Dr. Paul F. Eve, of Nashville, for fracture of the clavicle, which consisted in cutting down and wiring the fragments together with silver wire, closing the wound, and leaving it to unite. During the last five years of his life he succeeded in obtaining eminently satisfactory results in many cases.

Dr. W. T. BRIGGS, of Nashville, Tenn., remarked that the cases upon which Dr. Eve operated were those of ununited fracture of the clavicle, and that he merely suggested the operation for simple fracture of the bone.

Dr. GLENN remarked that he knew personally of one case in which Dr. Eve performed the operation for recent fracture, and with good success.

Dr. TURNIPSEED, in closing the discussion, remarked that the strap in front upon his apparatus was intended simply to keep the collars upon the shoulders.

CHRONIC DISLOCATION AT THE HIP-JOINT.

Dr. C. V. MOTHBAM, of Lawrence, Kan., reported a case of chronic dislocation at the hip-joint.

Dr. W. W. DAWSON, of Cincinnati, O., exhibited several specimens of

VESICAL CALCULI.

after which the Section adjourned, to meet on Wednesday, May 7th, at 3 P.M.

WEDNESDAY, MAY 7TH.—SECOND DAY.

The Section was called to order at 3 P.M. by the Chairman.

The minutes of the previous meeting were read and approved.

The first paper was read by Dr. I. N. QUIMBY, of Jersey City, and entitled

CONSERVATIVE SURGERY.

It consisted essentially of a paper formerly read before the Section at the Annual Meeting, held in Chicago, in 1877, the case at that time being incomplete.

Dr. LEWIS A. SAYRE, of New York, followed with a supplementary

REPORT ON THE TREATMENT OF POTT'S DISEASE BY MEANS OF THE PLASTER-OF-PARIS JACKET.

The report contained a complete analysis of one hundred and eleven cases, with extended reference to opinions expressed by eminent surgeons both in this country and in Europe.

The paper was discussed by Drs. T. Clay Maddux, of Maryland; A. C. Post, of New York; H. O. Marey, of Massachusetts; E. H. Dugas, of Georgia; I. N. Quimby, of New Jersey; W. A. Byrd, of Illinois; T. A. McGraw, of Michigan; and closed by Dr. Sayre.

On motion by Dr. Maddux, the thanks of the Section were tendered to Dr. Sayre for his valuable report.

AMPUTATION BY OPEN CONE-SHAPE METHOD.

Dr. J. E. LINK, of Terre Haute, Ind., read a paper upon the above subject, in which he claimed as advantages a better shaped stump and better results than by any other method; and also claimed that it was a method which originated with himself, and had not been adopted by any other surgeon.

Dr. W. F. PECK, of Davenport, Iowa, remarked that he had seen the same operation performed in Bellevue Hospital, New York, long ago, by Dr. James R. Wood.

The paper was discussed by Drs. Beck, of Ohio; Marey, of Massachusetts; Byrd, of Illinois; Quimby, of New Jersey; Garcelon, of Maine; Fuller, of Maine; and closed by Dr. Link.

URINARY CALCULUS WITH CONSIDERATION OF ITS HYGIENIC, ETIOLOGICAL, PATHOLOGICAL, AND SURGICAL RELATIONS—WITH FORTY-SIX CASES,

was the title of a paper read by

Dr. H. F. CAMPBELL, of Augusta, Georgia.

The bilateral method was the one employed in all the operations.

The paper was discussed by Drs. Dawson and Mussey, of Cincinnati, O., and Dowell, of Texas.

The Section then adjourned, to meet at 3 P.M. Thursday, May 8th.

THURSDAY, MAY 8TH.—THIRD DAY.

The Section was called to order at 3 P.M., by the Chairman.

The minutes of the previous meeting were read and approved.

ÉCRASEUR FOR REMOVAL OF UTERINE TUMORS.

A paper by DR. WILLIAM SCOTT, upon the above subject, was presented by the Secretary.

TREATMENT OF HEMORRHOIDAL TUMORS BY CARBOLIC ACID INJECTION.

was the title of a paper read by DR. J. R. WEIST, of Richmond, Ind., Secretary of the Section. Dr. Weist called attention to that method of treating hemorrhoidal tumors, believing that it was superior to any yet employed. The theoretical objections that had been raised against it were the occurrence of thrombosis and embolism. By a series of experiments, Dr. Weist had reached the conclusion that carbolic acid had almost no coagulable power upon blood within veins. A clear idea of the method and the substance of Dr. Weist's paper, aside from that mentioned, can be obtained by reference to vol. xv., p. 451, of the MEDICAL RECORD.

DR. A. C. POST, of New York, referred to Salmon's method, commonly known as Allingham's method, which had been performed many hundreds of times with almost uniform success in the practice of surgeons in this country, and regarded it as probably the most certain and the most safe mode of treatment at our command.

DR. W. A. BYRD, of Illinois, referred to dilatation of the sphincter by the closed hand so as to allow the pile above to get well at the same time with the cure of the ruptured sphincter.

DR. W. W. DAWSON, of Ohio, remarked that his surgical operations for piles had been uniformly successful. He used the knife for the external, the ligature for the internal pile, and he had not yet had an accident follow the patient. He thought one secret of success was *positive* strangulation of the pile. He had not found it necessary to paralyze the sphincter before the operation. With regard to the new method, if experiments proved that there was no danger from embolism, it might be a good method.

DR. J. W. MURPHY, of St. Paul, Minn., referred to twenty cases which he had treated by the use of carbolic acid injections, and with good results in all.

DR. H. W. BROWN, of Texas, remarked that he had been using the new method in preference to either the ligature or the knife. He used the carbolic acid as nearly pure as possible, simply diluting it with a small quantity of alcohol, and he threw only a few drops into each tumor.

DR. E. SMITH, of Detroit, Mich., referred to treatment of piles by transfixing the tumor with a hot iron.

DR. A. B. COOK, of Louisville, Ky., referred to his successful treatment of hemorrhoids by means of carbolic acid injections, and the form in which he ordinarily used it was one-half carbolic acid, one-fourth glycerine, and one-fourth distilled water. The solution with glycerine should be perfectly clear; if not so it was evidence that the acid was impure, and should not be used. He emphasized the importance of introducing the point of the needle *into* the cavity of the tumor, thus avoiding the sloughing which would follow injection of the cellular tissue.

DR. DAWSON emphasized the non-use of the knife in the treatment of internal piles, and thought that for the removal of old hemorrhoidal tumors something more radical than injections was required.

DR. A. C. POST thought that no *good* surgeon, at the present time, used the knife in the treatment of internal piles.

The next paper was read by DR. T. CLAY MADDUX, of Maryland,

ON THE NATURE OF GONORRHOEA,

and was referred without discussion.

PERITYPHLITIC ABSCESS OPENING INTO THE BLADDER AND THE RECTUM, WITH PATHOLOGICAL SPECIMEN.

DR. THOS. F. ROCHESTER, of Buffalo, N. Y., presented a pathological specimen of typhlitic abscess opening into the bladder and the rectum, with its clinical history. Of perityphlitic abscess he had had twenty-three cases, and in nearly all he had obtained an autopsy. It was usually excited by disease in the vermiform appendix. The foreign bodies which were found, and so frequently called grape-seeds, faecal calculi, etc., were in very many instances *gallstones*. In the case reported, the foreign body was originally a gallstone, as shown by analysis. The abscess opened into the bladder and the rectum, and the case was of about three years' duration. The patient asked for an operation, and the propriety of granting his request was fully recognized at post-mortem.

DR. A. M. POLLOCK, of Pittsburg, Pa., exhibited and described

A NEW INSTRUMENT FOR THE ADMINISTRATION OF ANÆSTHETICS.

It consists of a spiral cylinder open at both ends so as to freely admit atmospheric air. The specimen exhibited was about 8 inches in length by $4\frac{1}{2}$ inches in diameter, and was made of a simple brass wire coiled spirally. The cylinder was to be enveloped by a towel. Its advantages were economy, cleanliness, and safety.

The Section then adjourned. After the adjournment, Dr. Sayre, at the request of the Section, applied the plaster-of-Paris jacket to two cases of Pott's disease, for the purpose of giving the members a practical demonstration of the method of treatment.

SECTION ON STATE MEDICINE, PUBLIC HYGIENE, MEDICAL JURISPRUDENCE, CHEMISTRY, AND PSYCHOLOGY.

DR. JOHN S. BILLINGS, of Washington, D. C., Chairman.

DR. J. T. REEVE, of Appleton, Wis., Secretary.

TUESDAY, MAY 6th.—FIRST DAY.

The Section was called to order at 3 P.M., by the Secretary, who announced that owing to the temporary illness of Dr. Billings, it was necessary to elect a chairman *pro tem*. On motion, DR. J. L. CABELL, of Charlottesville, Va., was elected Chairman.

DR. A. N. BELL, of New York, announced the death of Dr. Wm. N. Compton, the former Chairman of the Section on Medical Jurisprudence.

DR. E. GRISSEM, of North Carolina, paid an eloquent tribute to the memory of Dr. Compton, who died while in the service in the late epidemic of yellow fever. The Chairman appointed Drs. E. Grissom, of North Carolina, J. M. Toner, of the District of Columbia, and F. Pratt, of Michigan, a committee to draft suitable resolutions and present them to the Association in General Session.

THE REGULATION OF MEDICAL PRACTICE BY STATE BOARDS OF HEALTH, AS EXEMPLIFIED IN ILLINOIS,

was the title of a paper read by DR. H. A. JOHNSON, of Chicago, Ill.

The paper was a full exposition of the thorough reform effected under the provisions of the new law.

DR. J. H. RAUCH, of Chicago, spoke of the success of the present system of regulating medical practice, and the good it had accomplished for the people gen-

cally, as well as for the profession in elevating its grade.

Dr. GIBON, of the United States Army, believed in the thorough regulation of the practice of medicine by the State, in such a manner as to prevent quacks from imposing upon the public, simply because they could show a diploma.

The discussion was prolonged at considerable length.

STATE MEDICAL SOCIETIES AND STATE MEDICINE.

Dr. S. E. CHAILLÉ, of New Orleans, La., read a paper upon the above subject, which, on motion by Dr. Bell, of New York, was referred to the Association in General Session. [See report of General Session, for Thursday, May 8.]

PSYCHO-PHYSIOLOGICAL HAND,

was the title of a paper read by Dr. E. SEGUIN, of New York City.

The theory of the paper was that, in cases of idiots, all education of intellect must begin by education of the senses. An interesting case was related.

The Section then adjourned, to meet on Wednesday, May 7th, at 3 P.M.

WEDNESDAY, MAY 7TH.—SECOND DAY.

The Section was called to order at 3 P.M. by the Chairman.

Dr. E. GRISSOM, of North Carolina, read a fitting memorial on the death of Dr. Wm. H. Compton, of Mississippi.

The resolutions accompanying it were seconded by Drs. Taylor, of Kentucky, and Browning, of Mississippi.

THE NEW PRINCIPLES OF PROTECTIVE (PRIVATE) SANITATION IN ITS RELATION TO PUBLIC HYGIENE,

was the title of a paper sent by Dr. H. R. STORER, of Newport, R. I., and read by Dr. E. S. DUNSTER, of Michigan.

The paper was referred to the Committee on Publication.

REPORT ON INTERVENTION OF PHYSICIANS IN EDUCATION.

Dr. E. SEGUIN, of New York, made some remarks upon the above subject.

On motion, the address of the Chairman was referred to the Committee on Publication.

Resolutions relating to the next census and the organization of the profession in all the States were then offered and adopted, and the Section adjourned, to meet on Thursday, May 8th, at 3 P.M.

THURSDAY, MAY 8TH.—THIRD DAY.

The Section was called to order at 3 P.M. by Dr. J. F. HIBBARD, of Indiana, the Chairman-elect.

Dr. S. E. CHAILLÉ, of New Orleans, La., presented resolutions looking toward the appointment of a committee on medical organization. The report was adopted. [See minutes of General Session for Friday, May 9th.]

THE MEDICAL EXAMINER SYSTEM OF MASSACHUSETTS, was the title of a paper read by Dr. F. A. HARRIS, of Massachusetts. It was referred to the Committee on Publication.

The Report of Dr. Billings, Chairman of the Committee on the question of hospitals, was read. It was accompanied by diagrams and lithographic illustra-

tions of hospitals for small towns, on approved plans. It was referred to the Committee on Publication, with instructions to consult with Dr. Billings with reference to the manner of publication.

Dr. ALBAN S. PAYNE, of Virginia, presented a paper on

THE TREATMENT OF SMALL-POX IN THE STAGE OF INITIAL FEVER,
after which the Section adjourned.

SECTION ON OPHTHALMOLOGY, OTOLOGY, AND LARYNGOLOGY.

Dr. HERMANN KNAPP, of New York City, Chairman.
Dr. A. W. CALHOUN, of Atlanta, Ga., Secretary.

TUESDAY, MAY 6TH.—FIRST DAY.

The Section was called to order at 3 P.M. by the Chairman.

Dr. E. WILLIAMS, of Cincinnati, was elected Honorary Chairman, and Dr. B. A. POPE, of New York, Vice-President.

IVORY EXOSTOSIS OF THE ORBIT.

Dr. E. WILLIAMS, of Ohio, read a paper upon the above subject, which consisted mainly in the history of a case. In future he would attempt to remove the exostosis without removing the eyeball.

IMPAIRMENT OF SIGHT PRODUCED BY EXCESSIVE DOSES OF QUININE.

Dr. O. H. VOORHEES, of Memphis, Tenn., read a paper upon the above subject, and referred to cases.

Dr. H. KNAPP, of New York, then gave

DEMONSTRATIONS OF ANATOMICAL AND MICROSCOPICAL SPECIMENS, AND OF INSTRUMENTS AND APPARATUS.

SYPHILITIC DISEASES OF THE CORNEA.

A prolonged discussion upon the above subject was held, after which the Section adjourned, to meet on Wednesday, May 7th, at 9 A.M.

WEDNESDAY, MAY 7TH.—SECOND DAY.

The Section was called to order at 9 A.M. by the Chairman.

CATARACT.

Drs. B. A. POPE, of New York, A. W. CALHOUN, of Georgia, and H. KNAPP read papers on cataract extraction, and a general discussion followed, which was participated in by a large number of members.

The Section, at 11 A.M., adjourned, to meet at 3 P.M. At 3 P.M. the Section was called to order by the Chairman.

The discussion of the subject of cataract extraction was continued.

AN OPERATION FOR THE CURE OF CYSTOID CICATRIX, was the title of a paper read by Dr. D. S. REYNOLDS, of Louisville, Ky. In the proposed operation a thread was passed through the cornea; and the author stated that he had never seen keratitis follow the operation.

CURE OF XEROPHTHALMIA BY OPERATION.

Dr. EUGENE SMITH, of Detroit, Mich., read a paper upon the above subject. The result of the operation was permanent union of the ball and the lids.

Dr. KNAPP, of New York, presented *pathological specimens*. One, a case of plastic cyclitis; the other

a ciliary body containing a chip of brass. A brief clinical history was given with the specimens. The Section then adjourned, to meet on Thursday, May 8th, at 9 A.M.

THURSDAY, MAY 8TH.—THIRD DAY.

The Section was called to order at 9 A.M. by the Chairman.

The Chairman read a paper

ON DISEASE OF THE MASTOID PROCESS.

The paper gave rise to prolonged discussion, which was participated in by Drs. Leartus Conner, of Detroit, Mich.; B. A. Pope, of New York; E. Williams, of Cincinnati, Ohio; A. W. Calhoun, of Atlanta, Ga.; E. Smith, of Detroit, Mich.; and A. H. Voorhees, of Memphis, Tenn.

There being no further business before the Section, it adjourned.

STATE MEDICAL SOCIETY OF ILLINOIS.

(Special report for THE MEDICAL RECORD.)

TUESDAY, MAY 20, 1879.—FIRST DAY.

The Illinois State Medical Society was called to order in Gillett's Opera House, Lincoln, Ill., at 10.30 A.M., May 20, 1879, by the President, Dr. E. P. Cook, of Mendota.

The Society was welcomed to the city of Lincoln with a very cordial address delivered by T. T. Beach, Esq.

Dr. E. Ingals, of Chicago, replied in behalf of the Society, in a manner which called forth unanimous applause.

After adopting the order of business for the meeting, the Society listened to the

ADDRESS OF THE PRESIDENT.

The paper covered a wide variety of topics, chief among which were discussions of the importance of sanitary science and State medicine, the adoption of the metrical system, and the ever-pressing subject of advance in medical education. While enforcing the importance of continual progress in all that can elevate the qualifications and standing of the profession, the orator refrained from insisting upon the adoption of any special measures for the accomplishment of these ends, other than those which the wisdom of those charged with the instruction and guidance of the public inside and outside of the ranks of medicine might devise.

AFTERNOON SESSION.

The business of the afternoon session was commenced with a paper by Dr. D. Prince, of Jacksonville, on

THE SANITATION OF SMALL CITIES—A RECOMMENDATION OF TILE-DRAINING AND SEWERAGE.

Prof. Owens, of Chicago, read the *Report of the Committee on Surgery*, consisting of a review of recent opinions regarding the treatment of hemorrhoids, furuncles, atony of the bladder, dislocation of the clavicle, Annandale's operation for the removal of tumors from the nasal passages, the antiseptic property of thymol, treatment of naevus, Hebra's method of dealing with rodent ulcer of the skin, Dupuytren's finger contraction, Callender's treatment of wounds without carbolic spray, surgical pathology of nerves,

skeletal measurements, a suit for malpractice in the treatment of a fractured thigh.

The paper was discussed by Prof. E. Andrews, who called the attention of the Society to the long recognized fact of the asymmetry of the human skeleton, to the value of ergot in enlargements of the prostate, to the treatment of lupus by scraping—he was in favor of the operation—the finger-nail forming the best instrument. The paper was further discussed by

Dr. Halker, who recommended the treatment of hemorrhoids by injection with liq. ferri persulph. He related a case of naevus on the breast of a young girl, also treated in the same way with success.

Dr. Prince recommended the treatment of lupus by galvanic cautery. He preferred the same method for hemorrhoids.

Prof. Hollister spoke of the histological changes which cause lupoid growths, and thought that removal of the entire morbid growth was necessary to success.

Dr. C. Truesdell, of Rock Island, then read a paper on the

TREATMENT OF FRACTURES OF THE FEMUR,

taking issue with the doctrine that such fractures must necessarily result in shortening.

Dr. Prince thought that equally good results might be obtained with almost any of the ordinary modes of treatment of these fractures.

Dr. Gill did not believe in the need of perfect coaptation of the extremities of the fractured bone when the dressing is applied.

REPORT OF THE COMMITTEE ON OBSTETRICS.

Dr. C. C. Hunt, of Dixon, presented the report of the Committee on Obstetrics—to the effect that little that was new had appeared in the literature of the subject during the past year. He, therefore, related his favorable experience of the use of hot-water injections in uterine hemorrhage.

Dr. Ingals recommended that the injection be thrown into the uterus instead of against the cervix.

REPORT OF THE COMMITTEE ON OPHTHALMOLOGY.

The report of the Committee on Ophthalmology and Otology was read by Prof. S. J. Jones, of Chicago.

STATE MEDICINE.

Prof. Lyman, of Chicago, read a paper on State Medicine, taking the ground that the ordinary duties of sanitary officials should be restricted to the public places and relations of a community, and that the private life of citizens should not be disturbed by the intermeddling of such officers.

WEDNESDAY, MAY 21, 1879.—SECOND DAY.

Committee on Nominations: A committee on nominations, consisting of one member from each county represented in the Society, was elected.

A committee of three was appointed by the President to recommend action by the Society relative to the passage of the bill now before the Legislature regulating the commitment of the *Insane to Asylums*.

This bill abolishes, in certain cases, a trial court for the commitment of the insane; indeed, in all cases except where such trial is demanded by the patient.

REPORT OF COMMITTEE ON PRACTICAL MEDICINE.

The Report of the Committee on Practical Medicine was presented by the Chairman, Dr. G. W. Jones, of Danville. The paper was a well-written and vivacious summary of the diseases and the therapeutical

measures with which general practitioners are most familiar. The reporter adopted in full the "germ theory."

CHLORAL AND THE BROMIDES IN OBSTETRICS.

DR. NORRED, of Lincoln, presented a paper on the use of these articles in obstetric practice, recommending them highly as a means of overcoming unpleasant nervous symptoms in such cases.

MEDICAL EDUCATION.

DR. E. INGALS, of Chicago, read a report on medical education, urging the limitation of medical charities, and an elevation of the standard of education, so as to reduce the number of practitioners and increase the emoluments of the profession. The writer advised a diminution of the number of the colleges, and their government by strong boards of trustees separate from the faculties, which should consist of numerous professors, well paid by funds secured by endowment, rather than by the fees derived from students, so that they might be independent of all desire to increase the number of students. The period of instruction should be not less than three years, with terms of nine months each. Graduates should be twenty-five years of age, and should have a good English education. The final examination should be held by boards of examiners, independent of the colleges, to be appointed, perhaps, by the State medical societies. A graded course of instruction was advised by the writer.

PROF. ANDREWS, of Chicago, read a paper entitled "THE CHIROPODISTS."

According to the doctor, the corn-doctors were improving in skill and respectability in such a way as to promise the final establishment of a specialty as distinct as that of dentistry.

PROF. HOLMES, of Chicago, read a paper on

TRICHIASIS.

The usual cause of that disease was chronic conjunctivitis, especially that form which produces contraction of the cartilages of the lids, stimulating the latent hair-follicles of the part. Sometimes the disease was caused by absorption of the inner margin of the lid, bringing its hairy border against the cornea. That, however, was not to be considered true trichiasis. The opinion of the writer was to the effect that simple removal of a portion of the integument of the lid would seldom result in relief of the difficulty. A very good operation consisted in splitting the lid into two flaps—the anterior, containing the integument, with its hair follicles, and the muscles of the lid. The anterior flap might then be moved upward on the posterior flap.

DR. HOTZ, of Chicago, had practised the method of making an incision parallel to the tarsal margin of the lid down to the cartilage, and then stitching the margin of the wound to the cartilage in such a way as to evert the cartilage. That often gave good results.

PROF. JONES, of Chicago, followed with some remarks upon the conjunctivitis which was caused by trichiasis, advocating the use of topical medication in these cases, instead of adopting operative measures, except as a last resort.

AFTERNOON SESSION.

The *Report on Gynecology* was presented by the Chairman of the Committee on Gynecology, PROF. FITCH,

of Chicago. The paper was a summary of the most recent opinions regarding the surgical treatment of lacerations of the cervix uteri. The author gave a full description of his own favorite method of operation, with notes of illustrative cases.

PROF. FITCH also exhibited a convenient apparatus for vaginal injections, devised by Dr. Lord of Plano, consisting in a modification of the fountain syringe and bed-pan.

REPORT ON NECROLOGY.

The Chairman of the Committee on Necrology, DR. WORRELL, of Bloomington, announced that owing to an accident his manuscript had been left at home. He desired to have the report passed, with permission to insert it in the Transactions of the Society. The request was granted.

MRS. PROF. STEVENSON, of the Woman's Medical College, Chicago, read a very interesting paper on

THE PHYSIOLOGY AND PATHOLOGY OF THE SYMPATHETIC NERVOUS SYSTEM.

The report was too much condensed to admit of any abstraction, and was a model of what may be done in the way of the application of physiological knowledge to the problems presented in the diagnosis and treatment of disease.

PROF. JEWELL followed with remarks on the anatomical relations of the sympathetic nervous system.

PROF. LYMAN called attention to the importance of addressing remedies to the nervous system in the nervous disturbances of diseases not primarily connected with that system.

TRACHEOTOMY IN CROUP.

DR. H. Z. GILL, of Jerseyville, read a paper on Tracheotomy in Croup, in which he gave all the accessible statistics of the operation as performed during the past year in the State of Illinois. It was illustrated by the exhibition of colored anatomical plates, and of the instruments used in the operation.

BILLS OF PHYSICIANS—EXPERT EVIDENCE.

The Secretary read a report from a committee to which, at the last meeting, was referred a communication from the Centennial Medical Society of Southern Illinois, calling upon the State Medical Society to take action looking to such change in the laws of the State as shall give the bills of physicians in case of last illness equal preference with the most favored claims against the estate of the deceased. Also to make provision for the adequate compensation of physicians who are compelled to make investigations and to testify in courts of law as experts. The committee presented a collection of legal decisions relative to the matter of testimony—notably the opinions of the Supreme Courts of Alabama and Indiana—and recommended that members of the medical profession should insist upon their rights in such cases whenever they occurred. The committee also recommended that a standing committee should present an annual report of all cases in which such claims might be adjudicated by the courts. As for matter of the last services in case of death, the committee recommended that the profession should use its individual influence with members of the Legislature to secure the necessary legislation.

The Treasurer, Prof. Hollister, presented his report, indicating a very healthy condition of the finances of the Society. The announcement of a balance of \$239 in the treasury was received with great applause.

REPORT OF THE COMMITTEE ON NOMINATIONS.

The Committee on Nominations reported the following: For *President*, E. Ingals, M.D., of Chicago; for *First Vice-President*, G. W. Jones, M.D., of Danville; for *Second Vice-President*, C. C. Hunt, M.D., of Dixon; for *Treasurer*, J. H. Hollister, M.D., of Chicago; for *Assistant Secretary*, Washington West, M.D., of Belleville. Place of meeting for next year, Belleville, Ill.

A full list of committees was also reported. The recommendations of the Nominating Committee were unanimously adopted by the Society.

EVENING SESSION.

DR. N. S. DAVIS, of Chicago, gave an interesting lecture of a semi-professional character, chiefly devoted to the relation of the profession to the community.

EXECUTIVE SESSION.

The Society then went into executive session. The Secretary read a series of resolutions prepared by Dr. Ingals to the effect that the Society request all regular medical colleges to institute preliminary examinations of students—six months terms of lectures, by the regular faculty, and that students be required to study five years before graduating. The resolutions were all adopted.

The Society then proceeded to nominate delegates to the American Medical Association, to the State Medical Societies of Indiana, Kentucky, Missouri, Iowa, Wisconsin, and Michigan.

The Chairman appointed Drs. Lyman, Rauch and Nesbitt a committee to draft a bill regulating the hygiene of school-houses, to report at the next meeting.

DR. WERRALL, of Bloomington, was appointed to report at the same meeting on the antagonism between malaria and phthisis.

A vote of thanks to the citizens of Lincoln and to Dr. Wilbur, of the Asylum for Feeble-minded Children, for their hospitalities to the members of the Society, was passed.

The President-elect, Dr. Ingals, was then introduced by the retiring President, Dr. E. P. Cook.

The Society then adjourned.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Special Meeting, April 14, 1879.

DR. A. E. M. PURDY, VICE-PRESIDENT, IN THE CHAIR.

THE RESPONSIBILITY OF THE MEDICAL PROFESSION FOR THE ABUSES OF MEDICAL SERVICES.

At a stated meeting, held March 24, 1879, Dr. F. R. STURGIS, house-physician at the New York Dispensary, read a paper upon the above subject, which was made the special order for April 14, 1879. The discussion was opened by Dr. Sturgis, who stated that the motives he had in view in bringing the subject before the profession were *twofold*. 1. The paper was intended as a purely medical address to medical men, calling their attention to the responsibilities which fall upon them for the abuses of medical charity; to show that trustees of dispensaries and the State Board of Charities had been interested in this subject; to show that there was a proposition to check, to a certain extent, the abuses which existed; to express the opinion that if proper authority was vested in the

house-physician the greater portion of the abuses could be checked; but to carry the plan into operation the co-operation of the attending physicians and surgeons was required. Some attending physicians and surgeons had objected to any special plan which looked toward the correction of abuses, and had said that so long as they had cases they did not care whether they were suitable persons for charity or not. If that feeling were general there would be no earthly use in calling attention to abuses of medical charity. But he hoped and believed that the medical profession were sufficiently alive to the fact that in their positions they were, to a certain extent, trustees, and were responsible for the abuses. 2. He hoped that this abuse could be corrected. It could not be done at once; time was required. Certain impressions must be corrected; and to do that, public opinion must be educated upon certain points. Many of the people were under the impression that the physicians were obliged to give them medical advice simply because they asked for it. In order to check abuses, concerted medical action was necessary. He thought it proper that the Medical Board of Dispensaries should have communication with the Board of Trustees, perhaps through the house-physician. The propositions he had laid down in the paper were suggestive rather than any particular plan. He believed that the subject should not be considered so much from a charitable point of view as from a politico-economical standpoint. He also thought that the charity-wheel was overridden to a very great extent, and that the sooner a large percentage of medical charity was swept away the better it would be for a correct understanding of the subject.

DR. O'SULLIVAN believed there was something wrong with the profession in this matter. There had been neglect, indifference, if you wish, to the entire subject. Why was it that the agitation of such questions was left almost entirely to a few? In that particular, physicians as a body were at fault, and failed to energetically push the question. The correction of the abuse must be reached through public opinion. The influence of prominent citizens should be secured; and if a united profession would grapple the subject, he had no doubt that success would be obtained.

DR. H. D. NOYES remarked that the practical points which Dr. Sturgis had brought to our notice in his paper were twofold: 1. The relation existing between the managing boards of public charitable institutions and the medical profession; and, 2. What measures could be adopted to prevent the unworthy from demanding charity in our public medical institutions. Upon the first question we were a few years ago thrown into great excitement by certain occurrences in the Presbyterian Hospital in this city; and the profession then arose in indignation. His own experience in connection with the management of public charitable medical institutions had been such as to lead him to have great respect for the managing boards. He had found that when they were approached in a proper manner, and reasonable propositions were laid before them, they were quite as ready to treat them with consideration as any other class of citizens. In the Eye and Ear Infirmary, an institution with which he had been connected for several years, when it was found that the management was becoming loose, a proposition was made that one of the medical staff should be selected to largely control the management of the institution with reference to the admission of patients. That office was created, and its functions had been carried out during the past five years with admirable results.

No reasonable request made by the medical man had been rejected by the general board of management. There was no doubt that a considerable number of persons who came were totally unworthy of charity, and were able to pay a certain amount of compensation. That was largely due to a faulty public opinion. It was largely a simple outcry of greed, an effort to save at the expense of some one else. It had perhaps also arisen from carelessness upon the part of medical men who attended in these institutions. That such was the case must be admitted; but he asserted that medical men, so far as his knowledge extended, had for years and years strenuously and persistently attempted to eliminate the persons who had no business to come there for medical advice. During the past year extra efforts had been made to keep from the Eye and Ear Infirmary those who did not belong there. Another observation: The medical profession was responsible for abuses in our public institutions in a sense to which allusion had not been made. A great many medical men said thoughtlessly to patients who gave them a little perplexity, "Go to a dispensary." He was unable to state how many times it had occurred to him to hear patients say, "Doctor So-and-so told me to come here." Such abuse was widespread, not only in the city, but throughout the country. While ready to give his services to those deserving of charity, he felt that a very great portion of the abuse of medical charity came from want of consideration upon the part of some physicians, and a desire to get rid of the case by sending it to a dispensary. He thought something like a "board of detection" was necessary in all public medical charitable institutions, in order to correct the abuses and prevent the admission of improper patients. The real remedy existed in the discovery of the facts relating to the financial condition of the applicant, but how they were to be always discovered he was unable to say. Another thought: Every physician in New York treated in his office a very large number of poor patients; but he was sorry to say that, while physicians were usually willing enough to treat people gratuitously, they were too often ashamed to accept a small fee. He believed that much of our difficulty regarding the abuse of medical charity would be obviated if those in high places, as well as those who did not have large incomes, were willing to accept small fees for their advice and treatment.

Dr. H. E. CRAMPTON remarked that until the hospitals and dispensaries could agree upon some definite plan of the management of medical charity they should not arrive at any satisfactory conclusion. He suggested that the simplest plan would be to have a salaried officer, paid by the institution for the district which he inspected, who should visit houses and receive applicants for medical charity, and that only those who came to the dispensary endorsed by such inspector should receive advice and medicine. In that manner all outsiders would be cut off, and all frauds would be more liable to be exposed. It would be a step toward the provident plan.

Dr. HENRY remarked that the subject under discussion involved the question whether young men should have the opportunity to live by their profession or not, and also whether there should be any progress in medicine, because the work necessary to such progress must be done by the young men. His impression, based upon nine years' dispensary experience, was that the abuses were, to a great extent, due to physicians themselves, and a willingness on their part to do the work without compensation. He also thought the Boards of Trustees were considerably to

blame. He decried appropriation of a single dollar of money to any but thoroughly organized dispensaries wherein medical officers had prominent places. If the profession would discountenance special dispensaries, and centre its influence upon the old and established institutions, the evil complained of could to a great extent be reached.

Dr. Henry then commented at some length upon the "outside affair" at the New York Hospital, and characterized it as the "biggest of humbugs," and an establishment erected "to elevate a few at the expense of many." If it was desired to reach the full inside history of the affair, ask the doctors of the New York Hospital, and "they would not answer;" "they were afraid of the influence of the trustees." It was only by having regular institutions, well endowed, and a fair representation of bold, good doctors in the Board of Management, that we should ever have them properly administered.

Dr. C. R. AGNEW remarked that the subject was one which must be carefully discussed in order to bring out the general principles involved, and so carry the feeling of the Society, and of the profession in every thoughtful, earnest, and non-selfish effort to correct what was certainly, in the language of the paper, "an abuse." It was not a new abuse, but was one which had floated down the stream of charity ever since attempts had been made by one man to aid his fellow-man who happened to be in a dependent position. The abuse of medical charity had grown, in a great measure, from: 1, the immense burden of pauperism cast upon us; and, 2, the great activity created in the study of medicine within the last twenty-five years, the latter bringing in vast numbers of men who were willing to serve in public institutions in order that they might have improved opportunities to acquire experience.

Dr. Agnew thought that if a move was made in the County Medical Society, simply with the view of securing "bread and butter" for ourselves, we should do injustice to ourselves, and should not accomplish the reform desired. He was sure that by such action our professional brethren would not be the beneficiaries. Success in obtaining a livelihood depended upon certain questions of political economy, and would be settled without much interference upon our part. As many would get a living as the market could afford, and no more. It was our duty to study the question so broadly as to cleanse the market, so to speak, and give the laborer a just opportunity. He thought that could be done by bringing those who were responsible for our medical charities to consider the subject in a thoughtful and scientific manner. He believed that ignorance was at the bottom of the abuse, and that, in general, the managers of charitable institutions were ignorant of the literature of pauperism. One of the first things to be done to correct the abuse of medical charity was *not* to give medical advice, or medicine, or lodging in a hospital bed to an individual who was financially capable of being attended to, and receiving benefit anywhere else. He believed that that principle should obtain in every department of charity, medical or otherwise. Nothing should be given to a poor man for which, if capable, he did not give some equivalent. The same principle should equally obtain in endowed hospitals. There was great danger to the cause of true charity from endowed hospitals. He believed that the door of every hospital or dispensary should be guarded by a cautious, lynx-eyed verger, who should approach the applicant with the spirit of a brother, and carefully uncover his financial condition. Then

the professional brother outside would obtain the benefit arising from the patronage of those who were unworthy of charitable aid. It could not be done by stamping our feet and attempting to coerce them, but by a scientific, painstaking, and patient method. It must be shown to them that there were certain principles upon which medical charity could be conducted without injury to the beneficiaries. That exceptional abuses would occur was inevitable; and they would continue to take place to the end of time. So long as men were in hospitals and dispensaries who were not experts, there would be persons who would studiously and consecutively lie to gain admission. He was entirely opposed to the principle of raising money, by excise or any other method, for medical charity in the city of New York. He thought it would not be persisted in when our institutions were more studiously managed with reference to the real necessities of their beneficiaries.

With reference to corporate dispensaries, it was, perhaps, an idea to be entertained; but he was quite sure if the members of the society could be induced to read the literature of the treatment of preventable pauperism, and the doctors in the dispensaries could be made to do the same thing, many of the abuses would disappear. The right kind of a man at the door of these institutions would be followed by an immense correction, for he believed there was as much veracity south-east of Tompkins Square as there was north-west of Madison Square.

DR. E. S. BATES believed that, in a great measure, too much charity was a curse rather than a blessing. He also believed that the physician should be compensated for his services in these institutions, the same as was the baker, the butcher, or the nurse, and that by serving without compensation the physician demeaned his profession, and contributed directly to the increase of crime and pauperism. A foundling asylum had been built to prevent infanticide, but the increase of illegitimate children in the city had been very great since it was established, and children found their way there from all parts of the country. For the abuse of medical charity, he believed medical men alone were responsible. If they would demand even a very small fee for their services, many of the institutions could not survive a single day—a result which was a desirable one. By continuing to give service gratuitously to these institutions, the medical men were encouraging pauperism and not relieving poverty. The poor we always had with us, and every honorable medical man was willing to do all in his power to alleviate their physical sufferings; but as medical men we should not continue to do those things which would make us all poor. Although it might not be possible to remove all the abuses, we might, perhaps, correct the medical.

DR. H. G. PIFFARD raised the questions, What *should* we do to correct the present abuse of medical charity; and what *could* we do to bring about the desired result? To the co-operative plan suggested by Dr. Sturgis he objected, on the ground that it would give rise to institutions among men who were not inclined to receive small fees, and would take business away from those who would be glad to render service for small fees, and the result would be, that the class of physicians just above must starve, or enter directly into the same competition. In other words, the greater portion of the younger physicians who had no capital to live upon, would be obliged to have their own private dispensaries.

The County Medical Societies possessed no power to prevent the formation of dispensaries. According

to the general law of 1848, any five citizens could organize a charitable institution.

He also thought that by exacting any fee for service or medicine, the dispensaries violated their charter. The tendency, also, of the small-fee system, was to invite patients to go to these institutions, who should go to physicians who were willing to prescribe for a small compensation. If any reform came, it must be by the united action of the medical profession. The suggestion made by Dr. Bates, that dispensary physicians should be paid for their services, was a desirable one, perhaps, but he thought the trustees of dispensaries would not consider the proposition for a moment, when they knew there were hundreds of physicians who were clamoring for the positions, and were willing to work for nothing. Not until every member of the profession would unite in saying that he would not serve without pay, could the rendering of gratuitous services be prevented. He favored the adoption of some system of inspection of applicants as recommended by Dr. Agnew. He also believed that the State should provide for its paupers as it provided for its criminals, and thought that if the dispensaries were under the management of the State, they would be productive of better results than at present were obtained. Dr. Piffard raised the question whether those physicians who held positions in dispensaries were not violating the code of medical ethics by advertising that they would prescribe for the poor gratuitously at stated times.

Many of the positions in the dispensaries were held by members of the profession in good standing who were *not* members of the County Medical Society. If any action was taken by the Society, it must reach its members. If such action affected positions in dispensaries, the society would be injuring its own members for the benefit of those who were regular members of the profession, yet *not* members of the County Medical Society. When all members in good standing in the profession were members of the County Medical Society, some action might be taken by which the entire profession could be governed; as it was, but little could be done. With reference to the New York Hospital Dispensary, the managers knew that it was detrimental to the profession. It was pretty well known that it was concocted to injure the profession, and yet there were men in the profession who assisted the managers in carrying their scheme into operation.

MR. HUMBER, a member of the Board of Trustees of Demilt Dispensary, remarked that what had been said contained truth upon all sides. For his own part he did not believe he was fulfilling his trust in making a charge, however small, to poor people, although his dispensary had adopted the plan. He believed when it was found that some money could be made by charging *ten* cents, consciences would become seared, there would be a yielding to the temptation, and the charge would be gradually increased. He believed that they were violating their charters by introducing the small-fee system, and certainly he was violating his conscience. The ten-cent plan had proved one thing, namely, that it would reduce the attendance of patients. To the mere fact of reducing the number of prescriptions he did not object, but that the plan diminished the attendance of the undoubtedly poor very greatly, must be conceded, else the institutions had been a lie from the commencement. He had made it a personal matter to see that no person went out of Demilt Dispensary without medicine who was not able to pay, and yet the easy application of the penalty had greatly reduced the number in atten-

dance of the *actual* poor, and it would soon be found that merely a provident dispensary remained.

DR. WILLARD PARKER thought the bottom of the subject had not been touched by anything which had been said. He hoped to be able to participate in the discussion on a future occasion.

DR. ZINZLER suggested a legal enactment making it a misdemeanor to obtain medical charity under false pretences.

DR. STURGIS thought that the really needy poor represented only a small proportion of those who visited dispensaries, and doubted if very many real poor patients were turned away by the adoption of the plan of paying ten cents. The object of the plan was to check the sturdy beggar and drunken vagrant from receiving the same benefit as the working widow obtained. It would reduce the number of patients, but that could not be avoided. He also stated that the question had been studied, and it had been decided that the charter was not violated by adopting the plan. He thought that *three* dispensaries could meet the wants of all the needy sick poor in the city.

DR. BEVERLY ROBINSON remarked that there were at one time some regulations governing the admission of patients to the New York Hospital Dispensary, which were considered objectionable, but that a committee was appointed which waited upon the governors, and, so far as he was aware, they expressed a wish to eradicate the objectionable features, and it was now understood that the visiting physician should endeavor to determine whether or not the patients were deserving of charity. Many patients were treated there who paid nothing whatsoever. He thought it was not the intention that patients were to be accepted upon the payment of the one dollar when their means were such as would enable them to secure medical aid elsewhere.

DR. PIFFARD remarked that he based his statement upon what had been told him by gentlemen who were familiar with the present regulations of the New York Hospital Dispensary.

DR. STURGIS remarked that he had based his statement upon what had been told him by gentlemen holding positions in that dispensary.

The Society then adjourned to meet April 21, 1879, when discussion of the same subject was continued.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from May 18 to May 24, 1879.

SHANNON, W. C., 1st Lieut. and Asst. Surgeon, Fort Clark, Texas. Granted leave of absence for one month, with permission to leave the Dept., to take effect when relieved from duty with 10th Infy., now en route to Dept. of the East. S. O. 101, Dept. of Texas, May 14, 1879.

KINSMAN, J. H., Capt. and Asst. Surgeon. Granted leave of absence from March 21, 1879, to September 21, 1879. His resignation, accepted by the President, to take effect Sept. 21, 1879. S. O. 117, A. G. O., May 17, 1879.

ERRATA.—Dr. John R. Hobbie writes, that in correcting his proof he overlooked the word "*inflammation*," 14th line from top of 2d col., p. 404, vol. xv., and that it should read "*deformities*."

Medical Items and News.

CONTAGIOUS DISEASES.—WEEKLY STATEMENT.—Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending May 24, 1879.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.

MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK.—Prof. John T. Darby has resigned the Chair of Surgery, and has been made emeritus professor.

Prof. J. Williston Wright has been elected to fill the vacancy caused by the resignation of Prof. Darby.

Prof. Wm. M. Polk, formerly Professor of Therapeutics, Materia Medica, and Clinical Medicine in the Bellevue Hospital Medical College, has, to fill the vacancy caused by the transference of Prof. Wright to the Chair of Surgery, been elected Professor of Obstetrics and Diseases of Women and Children.

CHICAGO MEDICAL COLLEGE.—Prof. E. W. Jenks, of Detroit, has been elected to the Chair of Gynecology, made vacant by the resignation of Prof. Wm. H. Byford.

THE NEW YORK ACADEMY OF MEDICINE.—At a stated meeting of the New York Academy of Medicine, held April 17, 1879, the following preamble and resolutions were offered by Dr. S. S. Purple, seconded by Dr. Austin Flint, and passed by the Academy, viz.:

Whereas, Abram Du Bois, M.D., of this city, a most worthy and generous benefactor of the medical profession, has given to this Academy the sum of five thousand dollars for the purpose of enlarging and improving the present building, therefore it is unanimously—

Resolved, That the Fellows of the New York Academy of Medicine recognize in this generous gift, again the noble qualities of head and heart which have, on more occasions than the present, moved the generosity and benevolence of the donor.

Resolved, That this Academy accepts with thanks this generous gift, and hereby declares its desire, and at this stated meeting orders, that Abram Du Bois, M.D., of the city of New York, be, and hereby is, declared a Benefactor of this Academy, and that his name be enrolled on its list as such for all future time.

Resolved, That this Academy, in its earnest desire to truly recognize in a proper manner, the magnanimity of the donor, hereby declares Abram Du Bois, M.D., an Honorary Fellow of the New York Academy of Medicine.

Resolved, That a copy of the foregoing preamble and resolutions be suitably engrossed and authenticated by the proper officers of this Academy, and forwarded to our most worthy benefactor.

Resolved, That these resolutions be published in the New York Medical Record and the New York Medical Journal.

[Signed] FORDYCE BARRER, M.D., LL.D.,
President.

H. T. HANKS, M.D., Recording Secretary.

WOMAN'S MEDICAL COLLEGE OF THE NEW YORK INFIRMARY.—The tenth annual commencement exercises of the Woman's Medical College of the New York Infirmary were held in the Union League Theatre, Thursday evening, May 22, 1879. The exercises were interspersed with music. The Hippocratic oath was administered to the graduating class by Dr. Emily Blackwell. The degree of Doctor in Medicine was conferred upon ten graduates by President Samuel Willets. The valedictory address was delivered by Miss Helen Maria De Witt, of New York, and reflected credit upon its author. The charge to the graduating class was delivered by Dr. Emily Blackwell, and was followed by an address by Mr. Aaron M. Powell, formerly editor of the *Anti-Slavery Standard*.

VETERINARY DEPARTMENT OF THE UNIVERSITY OF PENNSYLVANIA.—The Philadelphia Society for the Prevention of Cruelty to Animals has issued an appeal to the citizens of Pennsylvania for the foundation of a veterinary department of the University of Pennsylvania. Mr. Coleman Sellers, in an address accompanying the circular, says that in Great Britain and Europe the skilful veterinary practitioner is respected for his skill, and is recognized as a man of science. The time has come when this nation will either have to import from abroad men skilled in veterinary science, or it must take immediate steps to put it into the power of its own citizens to acquire the information needed to improve the sanitary condition of their domestic animals. It is estimated that the cows and the land to support them represent a money value of \$1,300,000,000. These animals yield 350,000,000 pounds per annum of cheese; 1,500,000,000 pounds of butter, which, converted into money, stands at \$350,000,000 per annum, only one-fifth less than the corn crop of the land. We are said to export \$13,000,000 worth of butter each year, and \$14,000,000 worth of cheese, while the ocean freights on these exports cost \$1,000,000, and the railroad freights, \$5,000,000 per annum.

BELLEVUE HOSPITAL MEDICAL COLLEGE.—Dr. Joseph W. Howe, formerly Professor of Clinical Surgery in the Medical Department of the University of the city of New York, has been elected Clinical Professor of Surgery in this institution. Dr. A. A. Smith has been appointed lecturer on Therapeutics, Materia Medica, and Clinical Medicine, to fill the vacancy caused by the resignation of Prof. Wm. M. Polk.

NEW YORK HOSPITAL AND DR. GURDON BUCK.—The New York Hospital has received by six of his friends a portrait of Dr. Gurdon Buck, whose term of service in that institution extended through forty years.

COLLEGE OF PHYSICIANS AND SURGEONS.—Dr. Henry B. Sands has resigned the "Chair of Anatomy," and Dr. Thomas T. Sabine has been elected his successor. Dr. Sands has been elected Adjunct Professor to the Chair of Surgery.

DR. CHARLES H. GIBERSON—MINUTE AND RESOLUTIONS.—At a special meeting of the medical and surgical staff of the Brooklyn City Hospital, held April 23, 1879, the following minute and resolutions were adopted:

Charles H. Giberson, M.D. died at his residence, 98 Remsen Street, Brooklyn, on Saturday, April 19, 1879, of acute idiopathic peritonitis, after a very brief illness of five days, in the forty-first year of his age. He was born in Bath, Carleton Co., New Brunswick, where he received the rudiments of his education. He began the study of medicine at Fredericton, New

Brunswick, subsequently pursued it at the Medical University of Vermont, and at the College of Physicians and Surgeons, New York, and was graduated with high honors at the former institution. He entered the Naval Service of the United States in October, 1861, as assistant surgeon, was ordered to the West Gulf Blockading Squadron, under the command of Admiral Farragut, and was attached to the Mississippi when she was burned before Port Hudson. In June, 1864, he was ordered to the marine rendezvous at New York, and was promoted to be passed assistant surgeon in 1865. In 1866 he was attached to the Susquehanna, flagship of the Brazilian Squadron, and was afterward ordered to the Peoria, belonging to the North Atlantic Squadron. He was on duty at New York Navy Yard in 1868, until Nov. 9th, when he resigned his commission in the navy and began the practice of medicine in Brooklyn. He took a deep interest in the advancement of medical science, was an active member of the Kings County Medical Society, and was largely instrumental in the establishment of its Pathological Section. He was also a member of the Medico-Historical Society and of the Physicians' Mutual Aid Association.

In 1877 he was appointed attending surgeon to the Brooklyn City Hospital, and held that position at the time of his death.

Dr. Giberson took an active interest in the patients who were under his care in the hospital, and brought to their treatment the same cheerful manner, the same deep interest, the same skilful insight, the same untiring and sympathetic devotion that he exercised toward those outside of the hospital, and was rewarded by like success both in the results of treatment and in the warm attachment that his patients felt for him.

In the death of our late associate, Dr. Charles H. Giberson, the medical and surgical staff of the hospital feel that they have lost the support and counsel of a skilful mind and conscientious associate in the wards of the hospital, and one who was devoted to the best interests of the hospital in all its departments.

Resolved, That they tender to the family of the deceased their sincere and deep sympathy in their sorrow.

Resolved, That a copy of this minute and resolutions be sent to the family of Dr. Giberson, and to the *MEDICAL RECORD* for publication.

S. FLEET SPEIR, M.D., *Secretary*.

CORRESPONDENCE OF SIR HENRY THOMPSON.—It is due to Dr. Van Buren and our readers to say that the letter from Sir Henry Thompson, which appeared in our columns last week, was prepared by him for publication, and was accompanied by an explanatory note from Dr. Van Buren, which, to our regret, was mislaid.

ERGOTINE IN OPHTHALMIA.—According to Dr. Planat, of Nice, ergotine makes an excellent and painless topical application in ophthalmia. He employs it dissolved in rose-water or glycerine, in the proportion of 15-22 grains to ʒv. Eight to ten drops of the solution are instilled into the eye every two hours. When there is chemosis, or when the inflammation of the eyelids is violent, a piece of linen soaked in the solution may be left over the eye for a few hours. According to Dr. Planat, even the most violent cases of blephar-conjunctivitis can usually be brought under control in two or three days by this treatment. In keratitis ergotine is less active than in the more superficial affections. In iritis it rapidly moderates the acute symptoms, and prevents the extension of the inflammation to the internal membranes of the eye.—*Le Lyon Medical*.

Original Lectures.

ON EPILEPSY.

A CLINICAL LECTURE DELIVERED AT CHARITY HOSPITAL.

By A. McLANE HAMILTON, M.D.

VISITING PHYSICIAN TO THE HOSPITAL FOR EPILEPTICS AND PARALYTICS.

LECTURE III.

(Reported for THE MEDICAL RECORD.)

GENTLEMEN:—The physical evidences of this very common disease presented by the patients before and after the attacks are few, and consequently the large number of cases brought before you to-day exhibit a much smaller number of interesting clinical features than those patients who were presented at my previous lectures, and their appearance has only a valuable statistical interest. Epilepsy, as we know, is a malady which, in all cases, implies a recurring loss of consciousness, with more or less convulsive movement as a feature of the attack. The special feature of the disease is this abolition of consciousness, and though the muscular movements may be so slight as to be scarcely appreciable, there is invariably, in true epilepsy, a suspension of the mental powers. It is well that you should remember this in cases which have a medico-legal bearing, for I do not believe that any act of violence which has been done while the individual is said to be epileptic or suffering from an attack of epileptic mania, can be excused unless there is at some time absolute unconsciousness or an epileptic derangement of the intellect. I should be loth, even in those cases, to pronounce the person irresponsible, unless the loss of consciousness had *preceded* the commission of the act of violence.

The loss of consciousness may be sometimes so transitory and irregular as to almost defy detection. Jackson, in his admirable Harveian lectures, calls attention to a form of the attack which he calls the *dreamy stage*, in which there is dual consciousness, or the phantom recollection of some past event or state, such as occurs when the individual unconsciously realizes that he has been in exactly the same state or position at a previous period. This I give to you as a suggestion of how fugacious may be the mental disturbance, and how important it is for you to be on the alert in recognizing these states which, in many instances, are the initial stages of the grave disease.

Now I wish to say a few words with reference to the use of the term epilepsy, for I am disinclined to believe that genuine epilepsy is as common as it is universally supposed to be; therefore to-day I will speak of both an *epileptoid* condition, which is purely symptomatic of various organic diseases of the brain, and *epilepsy proper* as indicative of an attack characterized by a classical train of symptoms which usually present the same mode of appearance in a great number of cases. It is of the utmost importance to make an intelligent distinction of this kind between symptomatic epilepsy, and epilepsy for instance arising in youth and pursuing a tolerably even course for a number of years. Of late the term has been employed by Jackson, Charcot, and many others to express many forms of motor convulsion; Jackson even holding that loss of consciousness is not an absolutely necessary feature of the attack.

Epilepsy proper, it has been found, begins in a great

majority of cases before the twentieth year in life, and in a variety of obscure ways. Many of the varieties of infantile convulsions which have formerly been roughly grouped under the head of eclampsia, in reality constitute the commencement of true epilepsy. Such convulsions may be lacking in certain features which go to make up a full attack of the developed disease, but they should always be looked upon with apprehension. In these attacks occurring in infancy, there may sometimes be but slight or momentary loss of consciousness, while the convulsive movements preponderate.

In other cases the condition may resemble *petit mal*, the attacks eventually becoming more pronounced and violent as they recur again and again. The child runs to its mother with a vague fear of some impending trouble, or stops suddenly in her play, her face becoming pale. These and other expressions are often the first indications of the disease. In these cases, intestinal irritation from worms, irritation from dentition, and various troubles of that kind are supposed to be the cause of the attack; but the convulsions have a deeper significance, and, though all exciting causes are removed, they recur from time to time to the discouragement of the physician and the parents. Several forms of epilepsy have been mentioned in the text-books, but for convenience we will only speak of the light attacks, or *petit mal*, and the severe attacks, or *grand mal*. These varieties may coexist, or they may occur independently. Of the twenty-odd patients brought before you, it will be found that about ten per cent. suffer from both forms, while in the remaining cases the severe form is the only one complained of. In fact, there may be a variety of motor expressions, some of which are but subjective; for instance, bearing in mind the fact that there may be a spasm of the muscular fibre of internal organs, as well as of the more gross masses visible to the spectator, it is reasonable to look for visceral and cardiac spasms, and the sensations described by the patient as forms of force expended internally.

It has been my experience in private practice, that pronounced epilepsy is much more common than *well-recognized petit mal*, although I have reason to think *petit mal* is by some supposed to be more common, although it cannot be denied that according to modern psycho-pathology there are numerous curious transitory mental states which are conceded to be epileptoid. An attack of *petit mal* may take a variety of forms. It may simply consist of a momentary loss of consciousness and some spasmodic movement of the arms, or, perhaps, only a grimace in which the eyes may be rolled upward. In one case, at present under treatment, the *petit mal* is associated with nervous cough which usually precedes the attack. In other cases the patient may be seized as he is walking across the floor, remain motionless for a second, and then go on as if nothing had happened. So, too, a species of *mental epilepsy* is very common, expressed by what might be properly called a spasmodic or discharging condition of the psychic centres, and as a consequence there are a variety of curious mental processes, attended, perhaps, by very slight muscular action.

It has been said that loss of knowledge of the attack when it has occurred, is one of the features of this disease, but this is not always true; for even if there be nothing to remind the individual that he has had an attack, such as injury from a fall, or destruction of articles he may be holding at the time of seizure, he is often cognizant of the attack, even though he may

not be so reminded by those in whose company he has been. This is especially the case if there has been an aura. In the more pronounced form of the trouble, I have, therefore, been often made to feel that the patients are by no means ignorant of the occurrence of the fit. Now in regard to the gravest attack, we may divide the convulsive seizure into four stages. These stages are not always well developed, either in a single paroxysm or in every individual.

The first stage is that of preparation, and it is in this that the warning or *aura* is felt, if it be present; but it is not, however, invariably complained of. The most common auras are those of a sensory character, and it will be found that a peculiar sensation starting from the epigastrium and travelling upward to the head, or from the distal end of one of the upper extremities in the same direction, will sometimes warn the patient of the approach of the convulsion; and of these four patients who have auras, in three it proceeds from the epigastrium. Sometimes the aura is of a vascular character, the patient's fingers becoming swollen and suffused with blood. In other cases the first intimation of an impending fit is the perception of some odor, which may be either offensive or agreeable. For example, some of these patients complain that they smell the odor of smoke before the occurrence of a convulsion; others are annoyed by a disgusting odor of decaying flesh, while the odor of flowers or spices is alluded to; and in one patient of whom I knew, the attack is preceded by the perception of the odor of peppermint. Jackson speaks of a patient who perceived a metallic taste as the precursor of the paroxysm.

With regard to the succeeding stage, that of the actual development of the fit, we may recognize at first the symptoms of anemia of the brain, and next those of cerebral congestion.

Bearing this knowledge in mind you will be enabled to diagnosticate the epileptic condition much more surely than by trying to remember the somewhat confusing list of symptoms published in the text-books. Either after an aura, or without any warning whatever, the individual falls to the ground and becomes convulsed by a tonic spasm of the muscles so that his body is either arched or bent to one side.

These phenomena are accompanied by great pallor, dilatation of the pupils, and almost complete arrest of respiration. After a few seconds the convulsion becomes clonic, the face becomes red and swollen, the pulse labored and hard, and the patient may void his urine and feces as a result of spasm of the bladder and rectum. During the clonic convulsion the respiration becomes exceedingly tumultuous and labored, froth oozes from the corners of the mouth, and if the patient has bitten his tongue the froth may be tinged with blood. This is a grave symptom, and has always a bad significance.

The commencement of spasmodic action is, as Jackson has shown, in the smallest muscles, usually of an extremity, and finally the convulsive action becomes extended. If the attack be light and the discharging lesion inconsiderable, but a small number of muscles will be involved; but if the cortical discharge be great, the paroxysm will be extensive.

After a period varying from thirty seconds to several minutes, the patient makes some sign of returning consciousness. During the continuation of these three stages he may twist his arms from side to side in a semi-voluntary manner and mutter unintelligibly, just as a person usually does who is recovering from the effects of ether. He may now, after lying for a variable length of time, gradually recover himself, arise and go about his duties; but more commonly he lapses

into a profound sleep amounting to stupor, which constitutes the fourth stage.

In the majority of cases the first stage is ushered in by a noise made by the patient. This noise may be either a shriek, the result of a purely mental process, or a smothered groan, which results from a forcible compression of the thorax and expulsion of air through the vocal cords. The latter sound is more common than the cry.

Of late, considerable attention has been paid to the form of convulsions occurring in an epileptic seizure, and Hughlings Jackson has announced the opinion that these should be divided into two forms: the tetanic, in which there is a preponderance of tonic convulsions, and tendency perhaps to opisthotonos and bilateral flexion of the forearms; and the epileptic or clonic convulsions, which consist in irregular movements. The former he supposes to be associated with disease at the medulla or posterior part of the brain, while the clonic convulsions are more symptomatic of anterior cortical disturbance. This, for some reasons, is a valuable distinction; but it seems probable, and I think a great majority of observers agree, that whether the primary nervous discharge originates in the cortex or at some other point, the medulla oblongata is the true seat of the active pathological change.

Now, with regard to the epileptoid attacks, and among these we may include the so-called syphilitic epilepsies, we usually find a decided irregularity in the expression of symptoms. In the epilepsy which is the result of syphilitic disease, there is undoubtedly a condition of meningeal disturbance of varying degree which exists between the attacks, and this patient who suffers from such a form of disease presents not only the initial expression of mental trouble, but he is at times decidedly deranged. A peculiar sluggishness of ideas and a sort of hebetude is highly suggestive of the specific nature of the trouble, and speech is slow and constricted.

Of course, this is a confirmed case, and we need not always expect such decided manifestation of the condition between the convulsions.

In syphilitic epilepsy there is very commonly headache of severe variety, which precedes the attack, and at the time of the occurrence of the paroxysm it is especially severe; while in ordinary non-specific epilepsy, if headache is present, it is always the result of the seizure.

Diplopia, hemiopia, cranial nerve paralyzes of various kinds, and attacks which seem to be expressed by much more violent convulsive movements upon one side of the body than the other, are most decided evidences of a syphilitic fit. The so-called "partial epilepsy" of Jackson and Bourneville is of this variety.

You will meet with cases of paralysis with which there is associated epilepsy, the paroxysm beginning in the paralyzed limb, or others in which there is no clonic stage, but simply a tonic spasm of one side; but this form is quite rare, and there are only two cases of which I know—both reported by Bourneville.

Epileptoid convulsions as the result of cerebral tumors are very often confused with the uncomplicated disease. Though it is not uncommon to find convulsive attacks unassociated with loss of consciousness, there are cases in which the seizure presents many of the features exhibited by the true disease.

In such examples it is well to use the ophthalmoscope, for the existence of retinal changes are frequently found, while local paralyzes, disturbances of locomotion, vertigo, headache, and vomiting will usually put one upon his guard as to the fact that

there is a brain tumor. In certain instances, epileptoid convulsions are symptomatic of cerebro-spinal sclerosis, even in its earliest stages when there are no other symptoms, and I have upon several occasions found attacks of this kind to be among the earliest symptoms of general paralysis of the insane.

It is hardly necessary to allude to symptomatic attacks occurring in the course of uræmic poisoning, for the error in diagnosis under these circumstances can only be made by one who sees the patient for the first time, or is entirely unfamiliar with his previous history.

Though the urine is sometimes tested in such suspected cases, and albumen is found, it is not well to be too positive in laying the blame upon the kidneys, for it has been found that a very common evidence of syphilitic epilepsy is the presence of albumen in the urine; but there will be discovered at the same time a decided deposit of phosphates. So this test alone is not sufficient. The appearance of the skin, the existence of œdema, and the symptoms found by ophthalmoscopic examination, such as retinal blanching or extravasations, will render substantial aid in such diagnosis.

The occurrence of the pronounced epileptic attack may be nocturnal, diurnal, and very often matutinal—or early in the morning upon awakening. As far as my experience goes, the nocturnal attacks are the most common. Of these patients before you, probably two-thirds have their attacks at night, although in private practice, or when patients are not closely observed, the occurrence of the night attack is frequently undetected. The staining of the bed-clothes either by bloody froth from the mouth, or by involuntary discharges from the bowels or bladder, or again, the bitten tongue, are often the only evidences which point to the occurrence of the night seizure.

Biting of the tongue seems to be much more common in the nocturnal variety of epilepsy than in any other, and, as has already been said, is a symptom of a very severe attack.

Besides the pronounced forms of epilepsy that I have detailed, there are several others of an irregular type which are rarely seen.

This woman upon my left presents, as the first indication of an attack, a curious disposition to run through the ward, entirely unmindful of what harm she does or who may be present, and manages to escape bodily injury in a way which seems almost miraculous. After a period of about two minutes she has an aborted attack.

In other instances the patient has run through streets for several blocks, or done a variety of curious things, apparently in an automatic manner. For example, Mesnet has reported the case of a soldier who, when given a pouch of tobacco and paper, automatically made cigarettes until the contents of the pouch were exhausted, and when started off at a brisk pace, marched to the end of the room, and, finding that he could go no farther, stood and marked time until stopped by his attendant.

Hughlings-Jackson relates a case of a gentleman who persisted in undressing himself upon a public wharf, and was only restrained with difficulty by his servants, and a few moments afterward knew nothing of what he had done. These and many other curious things familiar to nearly every one, are too often epileptic aborted paroxysms, and I am of the opinion that the "queer" actions of persons supposed to be suffering from incipient insanity, are, after all, epileptic manifestations, and this is strongly presumable if there be no further manifestations of insanity.

These cases are interesting, because they illustrate the fact that there may be utter loss of consciousness, but not necessarily a derangement of motor power expressed in convulsions, and they have especial significance in their medico-legal bearing.

The appearance of the confirmed epileptic is well shown in most of the cases before you. Some of them bear plentiful crops of acne as a result of the bromides, and this is one of the evidences of saturation; but, if you will look attentively, you will observe a peculiar lustreless, fishy expression of the eyes, which is quite striking. There is also a puffiness of the skin, which is of a dull muddy color. The lips have lost that clear red hue which is found in health, and they are swollen, and the lower lip is everted slightly. In some cases there is a low grade of conjunctivitis, and upon turning up the lids, you will find that the inner surface is granular. The lashes have fallen out in some cases, or are gummed together, while there is a disposition to lachrymation. In most of them there is an expression of sadness almost amounting to melancholia, while the faces of others bear an expression of vacuity.

As a consequence of epilepsy, there may be developed several interesting mental states, some of which are illustrated in the patients exhibited to you to-day.

The most familiar and constant state of mind-degeneration is imbecility, although this mental involvement is very often improperly recognized. On the other hand, it is confounded with idiocy, in which an epileptic condition is a symptom of the congenital condition, and not the result of an established disease. When we find imbecility or mental impairment after the period of childhood, it is usually an outgrowth of frequent attacks of *petit mal*.

An important fact bearing upon prognosis is, that very little mental impairment follows violent attacks occurring at infrequent intervals, but that numerous transitory losses of consciousness have a decidedly bad significance. Next in importance among the mental disturbances stands mania, and this may be either a symptomatic or a predisposing affection.

As to the etiology of epilepsy, it will be found that, above all other influences combined, hereditary tendency enters most largely into the causation of the disease; while, as exciting causes, disorders of nutrition, alcoholism, nervous excitement, uterine disease, and fright, play important rôles.

With reference to masturbation as a cause of epilepsy, I am not disposed to attach much importance to its etiological bearing. It is very common among epileptics, especially the class of patients found in hospitals and dispensaries, and is associated with other vicious tendencies which in confirmed cases render the chronic epileptic a very serious burden to society.

Homicidal tendency, stealing, destructiveness, and morbid impulses of various kinds are not infrequently found in patients who, before the commencement of the disease, had a useful career before them. On "the Island" numerous attempts have been made by epileptics to set fire to the buildings, and fights and brawls are of every-day occurrence.

With reference to the treatment of epilepsy, I have not much to say, for I take it for granted that this branch of neural therapeutics is familiar to you. I would, however, strongly advise you not to be too hasty in the selection of a remedy, for many have been recommended which have been proved to be utterly useless, and some have an undeserved reputation.

I would recommend, in the first place, a most careful observance of those hygienic rules which are of so much importance, and influence to such an extent

the progress of all the neuroses; and in the *second* place, would suggest the use of two or three remedies which seem to possess great virtue in this disease.

The bromides have received deserved popularity, and if used within proper limits and in combination, will sometimes cure cases of moderate duration, especially if the case is uncomplicated and is not the result of traumatism.

I am in favor of combining bromide of sodium with bromide of ammonium, equal parts of each, and of administering sixty grains of the combined salts together with thirty grains of hydrate of chloral daily. The doses should be divided so that the largest may be given a short time before the fit is likely to occur; that is, if any regularity in the occurrence of the convulsions can be distinguished. Of course, this quantity may be increased if occasion requires. In other cases, the bromides given in combination with bicarbonate of potash and some simple bitter tonic, as recommended by Brown-Séquard, will produce wonderful results. These remedies are especially serviceable in the nocturnal forms of the disease, and, in fact, are to be commended in the treatment of attacks of an irregular character.

I will caution you against giving the bromides with the mere idea of exhausting, as it were, or stamping out the disease. It is of the utmost importance to combine with them cod-liver oil or some other fat-making material which improves the nutrition of the nervous substance. It has been my good fortune in many instances, where the bromides have been given in excessive doses (even to the point of producing full bromism, and yet without producing any apparent effect upon the disease), not only to materially diminish the number of seizures by reducing the quantity of bromides administered—and giving cod-liver oil, cream, extract of malt, or linseed-oil—but to decidedly improve the patient's general health.

Should the cases, in which we have satisfied ourselves that there is no exciting cause to be removed, resist this plan of treatment, we may resort to the use of the actual cautery, or apply repeated blisters to the back of the neck. But in many cases even these remedies do but temporary good, and the result of our treatment must be discouraging.

From recent trials it would seem that curare is indicated in these obstinate cases, and a standard solution, acidulated with dilute hydrochloric acid, may be hypodermically injected every fifth day in doses of one-third of a grain until five or six doses are given. In the lighter forms of the disease the use of the fluid extract of ergot in drachm-doses, three times a day, alternated with tincture of belladonna in five-drop doses and gradually increased in quantity, afford very satisfactory results when the bromides are apparently inert.

Cannabis indica has also been recommended and successfully used by Sinkler, of Philadelphia.

If the disease has appeared in a patient over twenty years of age, especially when the characteristics of the disease are such as I have described when speaking of syphilis as a cause, we may use the combined iodide and bromide treatment, or better still the bichloride of mercury. One secret of success in the management of this form of the disease, and, in fact, nervous syphilis in general, is to push the administration of the iodides as far as we can safely go, and this must be done rapidly. Whatever you do in the treatment of this discouraging affection, be consistent and methodical. It is extremely injudicious to make changes and try new combinations when the patients are doing apparently well, or even some time when

no change follows, or to relax your vigilance over the invalid's personal habits. For epilepsy is essentially a disease, as I believe, in which there is a habit, if it may be so called. In many cases, in fact in a large proportion of all, there is a regular recurrence of the fit; and every day gained after the time when the attack usually occurs is to the patient's advantage, and helps to break up the tendency to regularity.

Original Communications.

THE INTRAVENOUS INJECTION OF AMMONIA.

By GASPAR GRISWOLD, M.D.,

HOUSE-PHYSICIAN TO BELLEVUE HOSPITAL.

DURING the winter of 1877-'78, while serving as assistant in the physiological laboratory of Bellevue Medical College, I made a number of experiments upon dogs with reference to the action of intravenous injections of ammonia. For this purpose I used the ordinary aqua ammonia (containing ten per cent. of ammonia-gas), diluting it with an equal bulk of water. This solution, if dropped upon the tongue, is highly pungent and irritating, but does not vesicate, the stinging sensation caused by it passing away entirely in a few minutes. I chose for experiment dogs in whom the viscera had been exposed for purposes of vivisection, and who had become exhausted with loss of blood and the depression attending the entrance of cold air into their thoracic and abdominal cavities. I waited, in such a case, until the heart had almost ceased to beat, its rhythm being disturbed, and its inefficient contractions no longer deserving to be called pulsations. I then injected into a convenient vein half a drachm of ammonia solution. After a period varying with the distance of the vessel selected from the heart, and with the rapidity of the circulation in the particular case, a marked change was observable. The heart had a moment before been dark and congested, its right cavities engorged, and the contraction of its fibres weak and uncertain. Suddenly the systole acquired a new energy, which emptied the distended right ventricle into the lungs, and filled the aorta with fresh oxygenated blood; the heart itself became bright red again as the new supply flowed in through the coronary arteries. It is impossible to do justice to the striking picture presented by these phenomena as they rapidly succeed each other beneath the eye of the experimenter. The circulation was almost immediately re-established, and the animal, if anesthesia were not too complete, moved and showed signs of life. In the course of fifteen or twenty experiments I never failed to obtain the result above described.

In my wards in Bellevue Hospital I have several times injected one drachm of ammonia solution into the veins of patients apparently moribund, and have always succeeded in stimulating them much more powerfully than I could do by other methods. The prompt and marked effect in some cases is almost startling to those who have been accustomed to see hypodermic injections of whiskey and ether, inhalations of nitrite of amyl, etc., employed to no purpose under similar circumstances.

On one occasion a man came in a great hurry, having been notified that his brother was dying of phthisis in one of my wards. Notwithstanding his

haste, the sick man was already moribund and unconscious when he arrived. Pitying his disappointment at being too late for a few last words, I injected a drachm of ammonia solution into my patient's cephalic vein. In five minutes the man who had appeared almost dead was sufficiently restored to speak, and half an hour elapsed before he again became unconscious. The effect of the stimulant was so marked that I had some difficulty at first in convincing the astonished visitor that his brother had not "taken a turn and was getting well again."

Case.—Man forty-five years of age, with cirrhosis of liver and ascites. Has been tapped three times, fluid reaccumulating rapidly; has grown weaker very fast during the past three weeks; now dying of asthenia; unconscious; pulse scarcely perceptible; surface cold and moist.

1st. Six half-drachm doses of whiskey administered hypodermically. No effect.

2d. Six half-drachm doses of ether administered hypodermically. No effect.

3d. Inhalation of ammonia. No effect.

4th. Inhalation of nitrite of amyl. Slight increase in force and rapidity of pulse. No sign of returning consciousness.

5th. One drachm of ammonia solution injected into a superficial vein of forearm. In twenty seconds increased action of heart. Pulse good at wrist. In three minutes patient answered incoherently something about being uncomfortable, and tried to turn on his side. Could be roused, and his attention attracted, for about fifteen minutes; then became unconscious again. Died half an hour later.

Case.—Moribund from phthisis. Unconscious; heart acting very feebly. Intravenous injection of ammonia caused the heart to act vigorously, and partially restored consciousness for about ten minutes.

Three cases, like the last, presenting no feature worthy of special description, but important as corroborative evidence.

The next case deserves more careful attention, being the first in which I have been able to observe the patient long enough to satisfy myself that no bad effects follow the injection of ammonia directly into the circulation.

Hester Mahar, aged forty-seven; Irish; single. Admitted to Bellevue Hospital, April 29th. On admission there was ascites, which had commenced a month before, and was probably due to cirrhosis of the liver. Right pleural cavity nearly full of fluid; heart displaced to the left. No evidence of cardiac or renal disease. Patient very weak, and compelled, from dyspnoea, to maintain a sitting posture. Abdomen tapped; seven quarts and eight ounces of clear serum withdrawn. Patient much relieved. Stimulants and nutritious diet ordered.

May 1st.—Patient very weak. Does not seem to suffer much from dyspnoea, though the right side is nearly full. Considered advisable to postpone thoracentesis until the patient is stronger.

May 3d.—Patient still very weak. Dyspnoea not marked.

May 4th.—Called by nurse to see patient. Found her breathing very little; weakness seeming to obscure the expression of dyspnoea. Almost unconscious. Cannot be made to notice anything, or swallow what is put to her lips. Fluids poured into her mouth run out again. Eyes vacant, pupils dilated; jaw fallen, tongue dry and brown.

Thoracentesis performed with the assistance of three members of the house-staff. Ninety ounces of clear serum drawn off. During the operation, which

lasted about twenty minutes, fifteen or twenty half-drachm doses of whiskey were administered hypodermically. In spite of these efforts at stimulation, the pulse, which had before been weak, disappeared entirely at the wrist. The impulse of the heart could scarcely be felt over the præcordia, and the respirations were shallow and ineffectual, not seeming adequate to the inflation of the lung just relieved from the pressure of fluid. The condition of the patient was so unpromising that my colleagues of the house-staff, who had been assisting me, were of opinion that she was dying, and that further treatment was useless, and even absurd. Expressing themselves to this effect, they left me, giving up the case in their own minds, and taking no further interest in the matter. While I was obliged to admit that the case was hopeless, judged by ordinary standards, and beyond the reach of ordinary stimulants, I could not help feeling that heroic measures were specially indicated. The source of trouble—fluid compressing a lung and displacing the heart—had been removed; if the patient could be stimulated to breathe deeply, and profit by its disappearance, there seemed to be good reason to hope for her recovery. Selecting a prominent superficial vein in the radial region, I exposed it by an incision through the skin. I then injected slowly into it a drachm of ammonia solution, taking care that the point of the hypodermic needle was free in the lumen of the vessel. This done, I placed my hand over the patient's heart and waited. In fifteen seconds I felt a marked increase in the force of pulsation. In about two minutes there was a strong pulse of a hundred, which was plainly perceptible at the wrist. A minute later the patient sighed deeply; the color came back to her lips; her eyes moved and began to show signs of returning intelligence. On being urged, she swallowed without difficulty two ounces of strong egg-nog. After a few deep inspirations, she breathed more regularly and easily; her pulse was strong and tense, ranging between 100 and 110. Half an hour afterward she was perfectly conscious, and reported herself comfortable, though weak. Pulse 90, regular and strong. Respirations 26, easy and natural. Swallowed easily and willingly small quantities of egg-nog. During the afternoon and evening patient continued to improve. Pulse 80-90, and strong. Respiration 20-30, and easy. Patient passed a good night, sleeping most of the time. Was bright and refreshed in the morning.

May 7th.—Steady improvement since last note. Sat up for two hours to-day and ate a lamb-chop with relish.

May 17th.—Patient sits up nearly all day and is gaining strength.

N.B.—Improvement has been uninterrupted since the injection of ammonia. No depression has been observed following the stimulant action of that remedy, nor has there occurred an unpleasant symptom which could be attributed to it.

The cases described seem to satisfactorily establish:

1. That the intravenous injection of ammonia is a prompt and powerful means of stimulation, acting efficiently in cases where other measures are of no avail.

2. That no bad effects follow its employment.

While the importance of the above deductions is obvious as a matter of general therapeutic interest, they seem to have a special significance in connection with those operations whose object is the removal of mechanical obstructions to respiration—I mean thoracentesis, and more particularly laryngotomy and tracheotomy. Thoracentesis is not, perhaps, very

often an emergency; but laryngotomy and tracheotomy, done in cases of croup, œdema glottidis, etc., generally fail to save life, because performed too late—the patient being too much exhausted to breathe in the air for which a new entrance has been made. Artificial respiration, hypodermics of whiskey and ether, cold affusions, etc., are resorted to in vain in many instances—the machinery of life cannot be set in motion again, and the cases die for want of efficient stimulation. Now, would not the intravenous injection of ammonia, in connection with artificial respiration, save many of these patients? It being proved that the treatment is without danger and followed by no bad effects, this question should not long remain unanswered.

In conclusion, I would call attention to the fact that it is not easy to perform intravenous injection through the skin. The vein collapses under the necessary pressure, and the needle is apt either to stop short and not enter the vessel at all, or to transfix it and direct the injection into the cellular tissue beyond. The only safe method to pursue is to dissect down upon the vein and expose it; the needle may then be carefully introduced until the point is felt free in the interior of the vessel.

A CASE OF SEPTICÆMIA FOLLOWING AN ABORTION.

By ISAAC OPPENHEIMER, M.D.,

NEW YORK CITY.

On Thursday morning, Oct. 3, 1878, I was called to attend Mrs. ———, æt. 26. She was at the end of the third month of pregnancy and had hitherto enjoyed the best of health. The day before she received a sudden shock by the jerking of a street-car over a stone on the track. She reached home feeling very well, but the next morning had severe pains and a sudden hemorrhage. When I reached her, the bleeding had greatly lessened, consequent upon the discharge of some thick pieces of flesh, as she described them, and which I took to be portions of the fetus and membrane. These, unfortunately, as is only too often the case, were thrown in the closet. Upon examination I found the external os well dilated and passing through the internal, easily removed some pieces of fetus and placenta already detached and ready for expulsion. Sweeping my finger over the fundus and not discovering anything, I removed some clots and gave a dose of Squibb's ergot, the uterus immediately contracting after removal of the debris. There was no more bleeding, and I left the patient in a comfortable condition, giving the usual directions as to rest and diet. She remained in bed until Monday, hemorrhage having entirely ceased and the uterus well contracted. She felt quite well at my morning visit, except that her appetite was not as good as on the preceding day, but still she was very eager to leave her bed. During the afternoon I was sent for and informed that Mrs. ——— had a violent chill, lasting about fifteen minutes, at eleven o'clock in the forenoon. Her temperature under the tongue was 105° F., pulse 120; face anxious, with a dark flush on cheeks; tongue furred, and great thirst. No pain on pressure over uterus, and no vaginal discharge; external os open to index finger, internal os contracted. Prescribed 20 grains quinine with 10 grains Dover's powder, to be taken in two doses, one hour apart.

Called about nine P.M., condition unchanged, except patient was partially cinchonized. Next morning

her temperature was 99½° F., pulse 100, perspiring freely, very pale countenance, tongue coated white, lips parched, and no appetite. At this visit I injected per vagina about a quart of sol. acid carbol. (5 j.—Oj.). In this condition she remained all day, perspiring excessively and feeling very weak, but frequently asserting that she was all right. I was under the impression that it was a malarial attack, though there was no preceding history of that disease. About five o'clock on Wednesday morning she had another violent chill, although a full dose of quinine had been taken the previous evening. When I saw her, her temperature was 103° F., pulse 110, and she presented the same symptoms that followed the first chill. Rejecting the theory of malaria, I determined to examine the uterus, as the symptoms might point toward a septic origin. Steadying the uterus with one hand, I introduced the index finger of the other through the external os to the internal, which I found quite contracted. By patient and gentle pressure it gradually admitted my finger, and, dilating it well, passed on to the fundus. Examining the fundus carefully, I felt several pieces of placenta closely adherent to the uterine wall. By careful scraping with the fingernail, I removed singly three pieces measuring altogether about one to one and a half inches in length.

The wall of the uterus was lined with a dark, foul-smelling fluid. I administered gr. ½ morphia and left the patient. The entire procedure lasted fully half an hour. The pieces removed were black at the edges, of foul odor, and, examined microscopically, were seen to be pieces of placenta in a granular condition. Upon visiting patient in the afternoon, I learned that she had a severe chill half an hour after the operation, but not as violent as the former ones. She was perspiring freely, skin clammy, and temperature 99° F., pulse 95. Pulse and temperature never rose afterward, and in twenty-four hours became normal without the aid of any medicine. She was very weak, however, and it was ten days before she could leave her bed, so depressing were the chills and excessive perspiration. This case presents some very interesting points. It is exceptional that so small a mass of placenta will give rise to septic trouble, and especially where there is no inflammatory or otherwise abnormal condition of the uterine walls. Usually in such cases, hemorrhage, often persistent for months, remains as the only effect. Among the poor, who are often unattended by a physician, this is only too common a result, and the sufferer is soon reduced, by the constant drain on her vitality, to an anæmic and exhausted condition, until compelled to seek medical advice.

On examining, when first called to my patient, the fragments were so small as to escape observation, although a careful search was made. This was due, probably, to the large clots in the uterus. Had the pieces of placenta been removed at once, all these dangerous symptoms would have been avoided.

Where a mass has been expelled before the physician arrives, and thrown away, he should examine the uterus from cervix to fundus, despite the assertions of the patient or attendant that all has passed away, for they will readily exaggerate as to the size of the expelled portion, so as to escape an examination. Sometimes clots will have been mistaken by them for the ovum which, perhaps, is still intact in the uterus. About three months before this I was called to a lady, who, in the third month of pregnancy, was seized with a sudden flooding, while receiving her guests. When I saw her, the maid in attendance informed me that she had thrown some large lumps, which had been expelled, into the closet. As the hemorrhage had ceased

upon my arrival, I supposed these to have been portions of the ovum, but on passing my finger through the dilated internal os, felt, to my astonishment, the sac entire and seemingly completely adherent to the fundus, for I did not stop to examine more minutely. No pains followed, no hemorrhage was induced, though she aborted some eight hours after. An almost similar case occurred in the practice of a neighbor of mine, who, feeling the ovum entire after a severe hemorrhage and where everything had been removed prior to his arrival, counselled complete rest. Contrary to his advice, the patient rose to go to stool a few hours afterward, and aborted almost immediately.

Another point of interest refers to the early appearance of the septic symptoms. At a meeting of the Academy of Medicine, held in February, 1876, during a discussion following a paper on "Unusual Uterine Hemorrhage," a number of well-known physicians stated that they never entered the uterus to remove the placenta after the expulsion of the fetus, but tamponed the vagina to control hemorrhage and assist dilatation of the os, and thus awaited its natural expulsion. If the placenta was not found on removing the tampon within twenty-four hours, the same procedure was renewed once or twice until expelled, and if not then, manual or instrumental removal was attempted. All danger of septic poisoning seems to have been ignored, for one speaker further stated that he allowed the placenta to remain six or eight days, if necessary, confining treatment to the use of the tampon. In the present case, septic symptoms appeared on the fifth day, and in a few days more the patient might have been beyond mortal help. The objections to removal of the placenta directly after expulsion of the fetus seemed to be: 1st. Non-sufficient dilatation of os internum. 2d. Inability to introduce the finger into the uterus, if not low enough in the vagina. 3d. Danger of incomplete removal of placenta. 4th. Injury to uterine wall.

As to the first objection, if the fetus has already been able to escape and hemorrhage consequently taken place, the os must certainly be sufficiently dilated to admit of a finger partially entering and dilatable enough to admit of its complete entrance with a little gentle and persevering pressure, no matter how well the uterus may have contracted.

Steadying and gently depressing the uterus with one hand on the abdomen, we can in most cases reach the fundus by introducing the finger only in the vagina. If unsuccessful, we can partially pass the hand, or, if necessary, introduce it entirely in the vagina. Should the pain be too severe, chloroform can be administered.

Steadying the uterus as described, the index finger is passed to the fundus and then the placenta scraped off. It is not often removed entire, but usually in two large and several smaller fragments. As soon as a piece is detached it is allowed to fall between the base of the finger and the uterine wall, and kept there while another piece is being separated. When all of the placenta is detached, the pieces are pressed against the wall of the uterus and so removed. It may thus be sometimes removed without once withdrawing the finger from the uterus, though usually two attempts may have to be made. After all is finished, a last examination is made, to be certain that no fragments have been left behind. The finger-nail makes a most admirable instrument, and causes no injury to the mucous membrane. It does not dig into, but only scrapes from its surface. Of course the hands are well cleansed and washed in a solution of carbolic acid before the operation. Thus the placenta can be

removed with entire safety. I have never seen any bad results follow, even when compelled to administer chloroform to introduce the hand into the vagina, nor discovered any by diligent inquiries as to the experience of others who have employed this treatment. Let it be remembered that our object is to prevent the occurrence of hemorrhage and septicæmia—either sufficient to destroy our patient, and if we can but accomplish this, we should not hesitate because the procedure may be painful or partake too much of the nature of an operation, especially since experience teaches that no bad results follow. How many women would have been spared months of hemorrhage and its disastrous consequences, if but, at the time of abortion, the uterus had been properly emptied?

It is remarkable how rapidly the patient's strength gave way. Eager to leave her bed before the first chill occurred, and although the disease was happily cut short, as it were, I do not believe that she could long have withstood the high temperature and profuse perspiration, liable as she was to secondary disease in some internal organ. With removal of the decomposing placenta, all dangerous symptoms soon disappeared. This proves that the septicæmia depends on the successive absorptions of a virus, each individual poisoning producing a set of symptoms depending on the amount absorbed. The later absorptions necessarily react on a system already enfeebled by the former poisonings, and so death may result from their combined effort alone, or from the altered condition of the blood producing secondary organic trouble. If the blood is at the first overwhelmed with the poison, death may rapidly occur. But this is very rare. The virus seems to be in a measure cast off in the chill, fever and sweat, and with a second introduction, the same set of symptoms recur. The combined effect of these repeated absorptions rapidly overwhelm the entire system, producing that condition known as the typhoid and death. Or death may occur, as before stated, from secondary organic changes, though this is not necessary, as many cases present, post-mortem, no lesions except a dark and fluid condition of the blood.

If, therefore, septic symptoms should follow an abortion, where fragments of placenta have for some reason been allowed to remain, the uterus must be immediately explored and the cause removed, in the hope that sufficient amount of poison has not as yet been absorbed to kill the patient. No matter how desperate the case looks, the attempt should still be made, and the following case, occurring in the practice of Dr. Whittall of this city, shows from what seemingly hopeless a condition the patient may still recover. When the doctor first saw his patient, she lay already in a typhoid state; her temperature was 105° F., pulse 150, cheeks dusky; there was low, muttering delirium; altogether the case seemed hopeless and fast approaching dissolution. There was that odor perceptible in the room and about the bed that too plainly showed the presence of decomposing matter in the uterus. As a last resort, the uterus was explored, and a mass about the size of a large egg, consisting of placenta and clotted blood, was removed. It was decomposing and gave off a disagreeable odor. When the patient was seen on the next day, to use the doctor's words, "she looked like a different person." Pulse and temperature were reduced, her delirium had disappeared, and she soon completely recovered.

Syringing out the uterus with disinfectants only temporizes. It cannot remove what is firmly adherent, and though it may prevent further decomposition, if

used early enough, the patient is liable to the same danger upon stopping the injections, and should no further septic trouble occur, the presence of ever so small a piece of placenta renders the patient liable to hemorrhage when convalescent. Besides, uterine injections, following an early period of pregnancy, often cause unpleasant symptoms, and, to produce a good effect, must be frequently renewed. In the latter stages of septicæmia, as in the case quoted, they can be of but little avail. Metritis should be no objection to removing the placenta, for it is masked by the greater danger, septicæmia, and in fact can scarcely be diagnosed in this condition.

Thus, many cases, otherwise hopeless, may be saved by a rational treatment, based upon the old law of a removal of cause producing a removal of effect.

Reports of Hospitals.

BELLEVUE HOSPITAL.

NOTES OF PRACTICE AND PECULIARITIES OF TREATMENT.

PNEUMO-HYDROTHORAX—QUESTION WHETHER IT WAS INCIDENT TO PHTHISIS OR TO EMPYEMA.

In the following case the question arose whether the pneumo-hydrothorax was incident to phthisis or to empyema. It was regarded as a question not easily settled if a case had not for some time been under observation.

A male patient, æt. 25, was admitted to the hospital December 7th. His family history was tolerably good, and was negative with reference to phthisis. He was suddenly seized with a chill, which was followed by pain in the side, dyspnoea, and symptoms which rendered it quite probable that he had pleurisy. After a time he began to expectorate muco-purulent matter.

Looking at the case from those symptoms, it could be fairly regarded one of pneumo-hydrothorax following empyema.

On the other hand, there was hoarseness, which had existed for some time independently of ordinary cold, and there was more or less expectoration of frothy white material with cough before he began to expectorate the muco-purulent matter. He then had a chill and pain, and it might be said that up to that time the case was one of simple phthisis.

There was no evidence of phthisical deposit at the apex of either lung. The patient was unable to lie upon his back or right side. The succussion sound had been obtained several times upon the left side, although at the time of this note it was absent. The case illustrated the fact that the succussion sound was occasionally temporarily absent in unmistakable pneumo-hydrothorax. There was absolute loss of vocal function on the left side of the chest, with flatness upon percussion, except over a very small space at the upper portion. The visiting physician was inclined to the opinion that the free incision was the best treatment for such cases.

EMPYEMA—ASPIRATION—FREE INCISION—MARKED IMPROVEMENT IN THE GENERAL CONDITION OF THE PATIENT.

A male patient was suffering from simple empyema. He had been aspirated, but with each aspiration it was evident that the purulent character of the

fluid was increasing. His general condition became very bad. Emaciation was rapid, and he had hectic. A free incision was made into the pleural cavity, and seventy ounces of pus were evacuated. The patient was almost instantly relieved of his dyspnoea and had been improving ever since the incision was made. Previous to the removal of the pus the heart was crowded far to the right, but it had returned to nearly its normal position. There was only slight cough with expectoration. A drainage tube had been used, although the visiting physician thought the cases did fully as well when treated simply by keeping the opening closed with a tent. The pleural cavity was washed out daily with carbolized water, one part of carbolic acid to two hundred of water. The daily discharge of pus was only three or four ounces, and in all respects the patient was improving.

PNEUMONIA—INDICATIONS FOR TREATMENT.

Three cases of pneumonia were seen, which were interesting with reference to the age of the patients and the indications for treatment as presented by the visiting physician.

CASE I.—*Single pneumonia occurring in a patient well advanced in years.—Recovery.*

A female patient, æt. 72 years, a native of Ireland, and a widow, was admitted to the hospital on the 19th of January, 1879. She was in the enjoyment of ordinary good health until the present sickness. On the 15th of January she was taken with pain in the side; there was no chill or vomiting. She felt that she was gradually growing weaker, and on the fourth day of her illness entered the hospital. At the time of admission her face was flushed, her respirations were 34, her pulse 98, and her temperature 104° F. There was evidence of consolidation affecting the lower lobe of the right lung.

On January 20th her morning temperature was 101° F., and afternoon temperature 103° F.

January 21st.—Morning temperature, 101° F.; afternoon, 102½° F.

January 22d.—Morning temperature, 100° F.; evening, 101° F.

January 24th.—Morning temperature, 99° F.; evening, 100° F. From that date up to January 28th the temperature remained at 99° F., and the patient was able to sit up. There yet remained evidence of consolidation of the lung.

One point of interest in the case was the mild course of the disease in a patient so old.

Pneumonia occurring in a person over seventy years of age usually proves fatal; but if not fatal, it is usually attended by symptoms more severe than those present. There were no cerebral symptoms. On the ninth day of the disease defervescence occurred, the temperature falling to 99° F., and remaining at or below that point. See treatment after the history of the following case.

CASE II.—*Double pneumonia occurring in a patient well advanced in years.—Recovery.*

A male patient, sixty years old, was admitted to the hospital January 11, 1879. He was taken sick on the 6th of January. The first symptom was a well-marked chill which lasted for one hour, and was followed by a febrile movement and sweating.

At the time of admission his pulse was 106, his respiration 46, and his temperature 103¼° F. There was evidence of consolidation of the lower lobe of the left lung.

January 13th.—Pulse, 112; respiration, 40; and

temperature, 103½° F. There was then evidence of consolidation of the lower lobe of the *right* lung.

January 14th.—Pulse, 102; respiration, 44; temperature, 104° F.

January 15th.—Temperature, 104° F.

January 16th.—Morning temperature, 101½° F.; evening temperature, 103½° F.

January 17th.—Morning temperature, 99½° F.

After that date the temperature remained at about 99° F., and the patient was soon able to sit up.

On the 14th of January, in addition to other symptoms, there was well-marked delirium.

In both instances the disease occurred in old persons. In one case the disease was ushered in by a chill; in the other the first symptom was pain in the side, and there was no chill. In both the temperature had preserved about the same course, ranging between 102 and 104° F., until the day of defervescence, when it fell to 99° F. and remained. In the first case there were no general symptoms, although there was a well-marked febrile movement. She was not delirious. She seemed quite comfortable, and the only symptom demanding especial attention was the condition of the pulse. It was not rapid at any time, but it was recorded as feeble; at one time it was very feeble.

In the second case, on the other hand, delirium for a few days was a prominent symptom. When the temperature fell the delirium disappeared.

With reference to treatment, it had been very mild in both cases. In the first case, the only indication for treatment was the condition of the pulse. The temperature, not rising above 104° F., was not regarded as excessive for a case of pneumonia. She took milk very well, and, to meet the indication for treatment given by the pulse, whiskey was given.

It was administered in half-ounce doses every hour at one time, and as her pulse increased in strength her general condition improved, and the whiskey was repeated every two hours, then every three hours, and finally discontinued altogether. Quiet in bed, nourishment by milk, and the administration of whiskey constituted the treatment in the first case. In the second case the indications for treatment were somewhat different. He was much more sick than was the woman. He had a more serious form of the disease, and cerebral symptoms for several days were well marked. His pulse, however, continued good throughout. But his tongue at one time was quite dry, and his general appearance was such as indicated a fatal termination. The treatment was very simple, notwithstanding the alarming symptoms. During the days when his temperature was the highest, quinine was given in full doses, but it was doubted whether it was of any special service. He also received a moderate quantity of whiskey. Although very sick, his pulse continued in fair condition, and for that reason only a small quantity of whiskey was administered. The chief items in treatment were rest in bed and the administration of as much milk as the patient could take. He had made a very comfortable recovery.

CASE III.—*Pneumonia occurring in a young man—Indication for treatment—Recovery.*

A young man with a large frame, and a general appearance as if capable, when well, of considerable physical endurance, was admitted to the hospital with pneumonia, involving one lobe of one lung. At the time of admission he was very uncomfortable. He complained of pain in the side, felt sick and restless, and his face bore an anxious expression. He was not delirious at any time, but was in a condition which suggested the development of delirium at any mo-

ment. His temperature reached 105½° F., and the pain in the side was severe. His pulse was not feeble, but full and rapid.

The indications for treatment were quite different from those presented in either Case I. or Case II.

Being a young man, he was not depressed by the disease, but felt the full effect of the febrile movement, and his pulse, instead of being weaker, was fuller and stronger than normal. He was very restless, suffered a good deal from pain in the side, and was very uncomfortable.

The principal indication was to make the patient more comfortable. It was believed that such a patient did not need quinine, although the febrile movement was marked. It was regarded as a case in which early general blood-letting would have been beneficial. Not that the course of the disease would have been shortened, but that the patient would have been rendered more comfortable, and at the same time would have recovered in the same manner in which he was recovering.

It was believed that such cases were benefited by another somewhat old-fashioned plan of treatment, and that was by the use of calomel and opium. Had he been treated by using pills containing calomel grs. ii., and opium gr. ʒ, repeated every three or four hours during the first two or three days of his illness, he would have been made much more comfortable, but the course of the disease would not have been changed. Instead of either of those plans of treatment, there was still another which had not received the demerit of being old-fashioned, and yet was very serviceable in many cases. It was to put the patient under the influence of aconite combined with small doses of opium. Much the same effect could be produced by that plan as by either bloodletting or the combined use of calomel and opium.

The last plan of treatment was adopted in this case, and the patient's restlessness was alleviated, the pulse was rendered less full and hard, and his entire condition was made very comfortable. Defervescence occurred in the usual manner, and convalescence was established.

The indications for treatment in all cases of pneumonia were placed under two heads:

1. To bring the case to a satisfactory termination, to prevent the death of the patient; and 2, to render the patient as comfortable as possible while the disease was running its course.

To meet those indications no routine plan of treatment was applicable to all the cases.

Defervescence might occur at any time from the second to the seventeenth or eighteenth day of the disease, when the pneumonia was left to pursue its course without any treatment whatever. In most cases the sudden fall in temperature occurred between the fifth and the eleventh day of the disease.

That fact rendered it very difficult to tell what effect treatment produced; to decide whether the results seen were due to the plan of treatment in use, or to the natural course of the disease. That was no reason, however, why an effort should not be made to meet the indications evidenced by certain symptoms.

In pneumonia, as in other inflammatory diseases, the patient required a liberal amount of nourishment, and to meet that indication milk was the best food that could be employed.

It was known that in pneumonia a feeble pulse indicated considerable danger, and that was to be met by the use of alcohol.

It was also known that if the pulse was contracting too forcibly, the condition of the patient would prob-

ably be improved by bringing the action nearer to the normal.

At the same time, at the end of every case there seemed to be considerable doubt with reference to the amount of actual benefit the patient had received from any treatment.

URÆMIA ASSOCIATED WITH ELEVATION OF TEMPERATURE.

It has been said that one of the diagnostic points to be considered in deciding whether in a given case coma is due to uræmia, is that in pure uræmia there is no elevation of temperature. The case before us was an exception to the suggestion, because there was marked elevation of temperature and well-defined uræmic symptoms, without any known inflammatory complication. The patient was at once put upon the use of digitalis, in doses of half an ounce of the infusion every two hours. Dry cups were applied over the loins, a drop of croton oil was administered, and ten minims of Magendie's solution of morphia were given hypodermically.

Progress of Medical Science.

BUCCO-PHARYNGEAL TUBERCULOSIS.—In a clinical lecture delivered at the *Charité*, Paris, Dr. Laboulbène gave the history of a case of this rare affection that had been under treatment for some time in his wards. On admission the patient presented consolidation and softening at the right apex, and an ulcer with sharply-cut, serrated edges, and a grayish base, situated on the right side of the hard palate, extending from the canine tooth to the posterior part of the gum. The upper gingivo-labial fold also presented some ulcerations, with slightly fungous bases. These ulcers were very painful; mastication was also difficult. Some yellowish points were discovered scattered along the borders of the ulcers. The diagnosis was tubercular ulcers of the mouth, and it was subsequently confirmed by the autopsy.

In the evolution of this affection, the initial stage is always overlooked. The patient presents a few grayish granulations on the bucco-pharyngeal mucous membrane, but there are no appreciable subjective or objective symptoms. The ulceration begins by removal of the epithelium, thus laying bare the granulation. This soon disappears, and then the painful stage begins. The contact of cold air, of wine, and of food, and the movements of the tongue, excite pain, which is sometimes so intense that the patient refuses all nourishment. The salivation is often very profuse. The glands in the sub-maxillary regions are never markedly enlarged, and are often perfectly intact. Later on, the patients present symptoms of pulmonary, abdominal, or cerebral tuberculosis. When examined with a strong light, the edges of the ulcers are seen to be elevated and scalloped. Some of the ulcers are round, and some serpiginous; some are old and others recent. Alongside the ulcers a number of yellowish points, or granulations, will be found. This is a pathognomonic sign. The ulcers are very persistent, but recovery is possible. The yellow granulations are always found in the recent ulcers, but may be wanting in the older ones. When enucleated, they are found to consist of a few connective-tissue fibres and minute elements, smaller than blood-corpuscles, containing nuclei that can with difficulty be seen. These granular ele-

ments are shrivelled and caseified embryonic cells, the characteristic elements of tubercle. When a section is made through an ulcer, the little vessels going to it are seen to be surrounded by rings of leucocytes, which finally completely obliterate the lumen of the vessel.

The diagnosis of this affection from other lingual ulcerations, and more especially from syphilitic and cancerous ulcerations, is often exceedingly difficult. The prognosis is, as a rule, unfavorable; even if the ulcers should be cured, the diathesis persists. In the treatment the general measures to be adopted are those indicated by the diathesis. Locally, the tincture of iodine, nitrate of silver, perchloride of iron, and emollient gargles have been found to be useful.—*La France Médicale*, Feb. 19th and 22d.

NATURE OF THE YELLOW FEVER POISON.—Dr. H. D. Schmidt, pathologist of Charity Hospital, New Orleans, has had numerous opportunities for investigating the nature of the poison of yellow fever. He takes a decided stand against the germ theory, claiming it to be a disease depending, like small-pox, scarlet fever, measles, etc., upon a specific poison of animal origin, a product of the diseased human organism itself. In support of this position, he adduces the immunity from a second attack, which it possesses in common with all other specific diseases. The pathology of the disease also distinguishes it from those affections in which a *contagium vivum* has been found, for in place of the venous congestion, ecchymosis, softening of the spleen, and loss of coagulability of the blood, which are characteristic of this class, we have arterial congestion, normal spleen, and retained coagulability of the blood, although the latter has been erroneously reported as lost. In severe cases hemorrhages may take place from different mucous membranes, but hemorrhagic effusions into the interior organs are but seldom observed. The most characteristic phenomenon, however, is the fatty infiltration or degeneration constantly met with in a number of organs. The poison emanates from the body of the affected individual only in the gaseous form, and in this form may be absorbed by another individual, or, adhering to clothes, bedding, etc., may be transported to distant places, and there become other centres for distribution. As in the case of putrefaction, septicæmia, the *poison increases in intensity with each individual through whom it passes*; explaining the fact that the fatality of the disease increases as the epidemic advances. No bacteria, or other living organisms, are found in the blood of patients in any stage of the disease. The prevention of the disease involves the interesting and unsettled question of quarantine, and the perfect isolation of the first cases would certainly appear to be the most important sanitary measure.—*New York Medical Journal*, May, 1879.

TREATMENT OF CLEFT PALATE.—The success of staphyloplasty should not be measured simply by the extent of union obtained, but the ultimate object of the operation, the improvement of the speech, should be kept in view. That union is frequently obtained cannot be denied, but Dr. Kingsley claims that the improvement of the speech is but a rare sequel, owing to the shortness of the velum preventing the closure of the posterior nares. To accomplish the desired object, a soft palate made of rubber is more useful, and he narrates a case in which this was done with success. The patient had been operated upon ten years before, and the cleft in the soft palate closed; anteriorly an opening in the hard

palate was closed by an obturator. No gain had been made, however, in articulation. A velum of soft rubber was now made and passed through the opening in the hard palate, the anterior extremity being fastened to the obturator. The only immediate effect was a change in the tone of the voice; but a few weeks under the care of an elocutionist produced a marked improvement.—*New York Medical Journal*, May, 1879.

IODINE IN THE TREATMENT OF MALARIAL FEVER.—In corroboration of Dr. Willibrand's assertion that iodine is a specific remedy for malarial disease, comes the evidence of Dr. J. W. Wadsworth, Saltillo, Mexico, who has treated over three hundred cases of intermittent fever with this drug. He has records of two hundred and sixty of these cases, many of them being chronic cases extending over various intervals of weeks or months. In the severe cases ten to fifteen grains of quinine were given at first, followed by compound tincture of iodine, ℥ x. to ℥ xv.; in the severest cases arsenic was added. In every case the paroxysm was arrested within twenty-four hours, and twelve doses, or four days of treatment, were sufficient to guarantee a cure, with the exception of eight relapses, six being on the fourteenth day, one on the twenty-first, and but one on the seventh. In not a single instance, though under the most miserable hygienic surroundings, did there occur a failure to effect an immediate cure, when the medicine was taken as directed. Quinine and arsenic have often failed the writer, but iodine never.—*New York Medical Journal*, May.

CHOLECYSTOTOMY.—This operation has been performed four times of late years; in 1876, by Prof. Bartholow, of Cincinnati, who aspirated a distended gall-bladder, and advised the exploration of the common and cystic duct in similar cases by passing a probe through the canula; in 1878, by George Brown, M.R.C.S., who opened into the abdomen, but failed to reach the gall-bladder; during the night, however, bile was discharged from the wound, and the woman subsequently recovered; the case of Dr. Sims, published in the *British Medical Journal*, June 8, 1878, was the next, and to him is due the credit of placing this on the basis of a deliberate operation in the surgery of the abdomen. Dr. Keen's case was published in the January number of the *American Journal of the Medical Sciences*. Petit, however, read a paper on this subject in 1733, and mentions some reported cases. Le Dran, Morgagni, and others speak of it as a proceeding to be considered under certain circumstances. In 1859 Dr. Thudichum suggested "performing an operation for the extraction of these foreign bodies (gall-stones) either in a direct manner or by forming a biliary fistula, and adopting a lithotriptic proceeding."—*American Journal of the Medical Sciences*, April, 1879.

QUININE AND THE CEREBRAL CIRCULATION.—From the experiments of Cleirone, of Naples, published in the *Gazette Hebdomadaire* for 1875, taken with a series of experiments made by Dr. Hammond, Dr. Mary Putnam Jacobi draws the following conclusions: 1st. Quinine in small doses (seven to fifteen centigrams) causes active dilatation of the external cranial circulation of the rabbit. 2d. In larger doses this was more slowly produced, but when produced was much more persistent. 3d. In the trepanned rabbit this effect was much more slowly produced, and only at much larger doses. It was then as persistent as in the non-operated animals. 4th. Dilatation of the aural blood-vessels may be produced, while those of the pia mater remain absolutely un-

changed.—*The Richmond and Louisville Medical Journal*, May, 1879.

EFFECTS OF CONSTIPATION UPON RECTUM AND ANUS.—Physiologically, the rectum is always empty, except shortly before the regular time for defecation. At this time the sigmoid flexure passes its contents into the rectum, and that uneasy sensation which is recognized as a call to evacuate the bowel is then experienced. If this call is resisted, a reversed peristaltic motion is excited in the walls of the rectum, and the fecal matter is returned to the flexure. When this neglect becomes habitual, the rectum ceases to empty itself completely and becomes a reservoir for fecal accumulations. Atony of the muscular wall results, the lining membrane of the gut hangs loose and flaccid, the whole pelvic circulation is interfered with, and hemorrhoids form. In this condition a drastic cathartic empties the bowel and forces the relaxed mucous membrane through the anus, where it is grasped by the sphincters; congestion, ulceration, and even sloughing of the entire constricted portion now result. The relation of cause and effect, though not always demonstrable, very frequently exists between constipation on the one hand, and fissure of the anus, abscess of the rectum, fistula in ano, internal and external hemorrhoids, prolapsus recti, stricture, and polypus of the rectum, etc., etc., on the other. It is a fact not sufficiently dwelt upon in this connection, that it requires but a short sojourn in the rectum to cause absorption of the fluids in the feces, and to render the remaining matter hard and dry. Consequently, when the office of the large intestine has become deranged, and the natural disposition of the feces interrupted, the rectum may contain dry fecal matter during the greater part of the time, notwithstanding that there seems to be a sufficient motion daily. In such cases the addition of water to the contents of the intestine is imperatively indicated. The bowel can be solicited to re-establish the suspended function, and the dry, hard, fecal matter can be softened by the daily use of an enema. In this way both indications can be met, and in the vast majority of cases a cure established.—R. A. VANCE, M.D.—*The Cincinnati Lancet and Clinic*.

ON ACUTE LEUCOCYTHEMIA OCCURRING IN DIPHTHERIA.—Prof. Bouchut made daily enumerations of the blood-corpuscles in all the cases of diphtheria that came under his observation within a period of six months, the number of analyses amounting to 177, and from the results obtained he has deduced the following conclusions: In severe septicæmic diphtheria there is always an acute leucocythæmia, which increases as the disease progresses, and diminishes when convalescence sets in. On the other hand, in the mild cases of diphtheria without septicæmia, there is no leucocythæmia, and the children always recover. In twenty-four cases, studied day by day throughout the whole course of the disease, the number of white globules varied between 5,000 and 10,000 in twelve out of ninety-three analyses, and between 10,000 and 100,000 in the other eighty-one, the average being 26,824. Prof. Bouchut insists on the necessity of daily examinations of the blood, as the number of white globules may be normal in one day and greatly increased in the next. He claims that valuable prognostic data may be gathered from these examinations, a rapid increase of the white globules indicating the occurrence of septicæmia, and pointing almost positively to a fatal termination, while a persistence of the normal relations between the red and white globules indicates a mild form of the disease, and almost certain recovery.—*Gazette des Hôpitaux*, Feb. 18th, 1879.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, June 7, 1879.

CROUP AND DIPHTHERIA.

As long as the relationship between these diseases continues to be an unsettled question, discussions concerning them will have both interest and importance. For, there is no nosological dispute that involves therapeutical measures so closely in its decision. This fact, together with the circumstance that important contributions to the subject have recently been made, are a sufficient excuse for presenting what has been so repeatedly made the subject of discussion.

About two years ago the Royal Medical and Chirurgical Society appointed a committee to inquire into the facts concerning the etiology, relationship, etc., of these two diseases. Their report was recently presented; and, although it has not yet been printed for distribution, the general character of it has been sufficiently made known. They were directed to inquire as to whether membranous laryngitis existed as a separate disease from diphtheria, and, if so, whether there were any clinical or pathological criteria by which it could be recognized. The report was to embrace also the etiology and general course of the diseases. No especial reference was called for in regard to their morbid anatomy; and the fact that no distinction between the diseases can be made on such a basis seems to be generally acknowledged.

The committee have carefully and laboriously carried out the instructions given; and their report not only covers the grounds above mentioned, but contains an appendix, in which is furnished a digest of the replies to queries sent out to a great number of practitioners.

The conclusions of the committee, as well as the evidence furnished by the queries, we may as well state at once point towards a belief in the non-identity of the diseases, or to the belief that there may be a laryngeal croup which is not due to diphtheritic poison. In connection with such conclusion, it is im-

portant to remember the definition which they give of the two diseases. Croup, they say, is a term signifying a laryngeal obstruction in children, accompanied by a febrile movement, which may or may not be attended by false membrane. Diphtheria is a zymotic disease, accompanied by membranous exudation, and which may or may not be attended by croup. These definitions were not provisional, or adopted previous to the investigation, but represent rather their conclusions, which are further and more definitely expressed in the statement that "croup may be membranous or not membranous, due to diphtheria or not so." The very strong leaning towards duality in these expressions is, however, modified in other parts of the report; and it can be seen that the document is a compromise between the somewhat conflicting opinions of its members.

The question of identity has been considerably narrowed since, some five years ago, it began to be actively discussed, and it may be well to re-state it now. Physicians had for a long time met in their practice two classes of cases, of which a notable and common feature was a membranous exudation in the throat or larynx. The one was a contagious, asthenic disease, attacking adults occasionally, with the false membrane deeply imbedded in the pharyngeal mucous membrane, and attended with albuminuria, and followed by nervous sequelæ. The other appeared to be a sthenic, non-contagious disease, characterized by a superficial membranous exudation in the larynx, occurring only in children. The latter was a local inflammation only, while the former was a specific constitutional affection. In defence of the duality of these diseases, a difference in the character of the exudation was at first claimed; but this claim is, as we have stated, now generally abandoned. The question then rested on the differences in clinical history. The albuminuria of diphtheria was evidenced as characteristic, but albuminuria was shown to occur sometimes in croup; the contagiousness of diphtheria was presented, but it was urged that diphtheria itself was not always contagious. Further, the asthenic character and paralytic sequelæ of diphtheria were asserted to be not always characteristic of diphtheria, and were sometimes characteristic of croup. The force of many of these assertions had to be admitted by the advocates of the non-identity of the diseases, and it has been pretty clearly shown that many of the cases that have been considered croup were really cases of diphtheria, and that the former disease, if it did exist at all, was of rare occurrence. The dispute, indeed, seems to have now narrowed down to the question whether membranous laryngitis is always caused by the special poison of diphtheria. In asserting the affirmative, the advocates of identity make a very sweeping statement, and throw the burden of proof upon themselves. It seems to be very well established that a traumatic membranous laryngitis may be set up by ammonia, steam, foreign bodies,

etc.; and the claim that the exudation in these cases is only and always an eschar, is not, we believe, well sustained. If, then, membranous laryngitis can be excited by irritating agents of such gross character, why not by the more impalpable ones of atmospheric or telluric, but not necessarily diphtheritic origin? Thus the question stands, and the committee have furnished no evidence to settle it. Some time ago, in discussing this same question, we stated that the evidence then rather pointed towards the identity of the two diseases. That this is in general the case, we are still disposed to believe, but as yet it can by no means be asserted with certainty that the membranous laryngitis of children is always produced by the diphtheritic poison.

PREVENTIVE MEDICINE.

THE old adage, "an ounce of prevention is worth a pound of cure," is pregnant with practical common sense. It is as equally applicable in the practice of medicine as in any other pursuit or profession, and receives the endorsement of the most experienced in the ranks of the medical profession. It is so much easier to keep out of the whirlpool by avoiding the rapids which lead directly to it, than by effecting an escape after once having entered them, that we give in full the words of one of the Nestors in our ranks upon this important subject. Dr. Samuel D. Gross closed his oration, delivered at the dedication of McDowell's monument, in the following significant words:

"Young men of the Kentucky State Medical Society, listen to the voice of one who has grown old in his profession, and who will probably never address you again, as he utters a parting word of advice. The great question of the day is, not this operation or that,—not ovariectomy or lithotomy, or a hip-joint amputation, which have reflected so much glory upon Kentucky medicine,—but preventive medicine, the hygiene of our persons, our dwellings, our streets—in a word, our surroundings, whatever and wherever they may be, whether in city, town, hamlet, or country, and the establishment of efficient town and State boards of health, through whose agency we shall be the better able to prevent the origin and fatal effects of what are known as the zymotic diseases, which carry so much woe and sorrow into our families, and often sweep like a hurricane over the earth, destroying millions of human lives in an incredibly short time. The day has arrived when the people must be roused to a deeper and more earnest sense of the people's welfare, and suitable measures adopted for the protection as well as for the better development of their physical, moral, and intellectual powers. This is the great problem of the day, the question which you, as representatives of the rising generation of physicians, should urge, in season and out of season, upon the attention of your fellow citizens,—the question which,

above and beyond all others, should engage your most serious thoughts, and elicit your most earnest co-operation. When this great, this mighty object shall be attained; when man shall be able to prevent disease, and to reach, with little or no suffering, his threescore years and ten, so graphically described by the Psalmist, then, but not until then, will the world be a paradise, with God, almighty, wise and merciful, in its midst, reflecting the glory of his majesty and power, and holding sweet converse in a thousand tongues with the human family."

Reviews and Notices of Books.

THE PRINCIPLES AND PRACTICE OF GYNÆCOLOGY. By THOMAS ADDIS EMMET, M.D. Henry C. LEA, Philadelphia.

THE profession has long been looking to Dr. Emmet for some authoritative statement of his opinions and practice in the department which he has done so much actively to create. The volume before us is therefore sure to meet with a host of readers. The limits of this review preclude any attempt to give a complete synopsis of the work. The reader will find in its pages a full measure of that ripened experience which furnishes a book its real right to existence.

Chapter I., On the Relations of Climate, Education, and Social Development, contains some useful warnings and excellent advice. The opening sentence is rather lugubrious. "A thinking man," it states, "who has had opportunities for observation, cannot divest himself of the apprehension that the physical development of the women of our land is becoming deteriorated." It is, however, a great comfort to remember that, from the earliest history of our race, no thinking man ever did divest himself of gloomy apprehensions regarding the future of posterity. At any rate, coming as we do from a section of the country where men and women have the trick of nearly outliving the century, we have our suspicion that the sentence quoted is moonshine. Dr. Emmet does not, however, often treat the reviewer to an opportunity for criticism.

Chapter II., On Instruments used in Examinations, and Chapter III., On Surgical Instruments and Appliances, furnish a useful key to the pages which follow. The description of the vaginal tampon should be carefully studied. Chapter IV., On Modes of Diagnosis, is clear, and likely to prove of service to beginners. Chapter V., On Causes of Disease, Reflex and Direct, contains the following statement: "The female who has passed her life in celibacy is more liable, after the age of thirty, to suffer from the development of a fibrous tumor than the sterile, while the sterile is more liable than the fruitful woman." This conclusion is drawn from an analysis of 239 cases, and is interesting because a similar analysis by Winckel of 555 cases led him to a precisely opposite result.

The sixth, seventh, and eighth chapters are devoted to general treatment. They are explicit, and the recommendations in them will be subjected to an extensive trial. The triumph of hot-water injections in uterine affections is Dr. Emmet's own work. In 1853 Trousseau reported two cases in the *Gazette des Hôpitaux* (No. 33), in which the hot-water douche was

employed to control uterine hemorrhage. The hemorrhages were due respectively to abortion and cancer. The treatment was successful. The reporter of the cases states that Trousseau was led to a trial of the hot water by noticing the difference between the hands when one is placed in water at 104° while the other is immersed in water at the freezing point. The contrast between the bloodless condition of the former and the congested appearance of the latter after prolongation of the experiment, led to a trial of the hot water in uterine hemorrhage for the sake of obtaining its permanent secondary effects. Trousseau's idea was received with small favor at the time, and soon passed into oblivion. The fact is only brought up here to show the contrast between a happy thought and the patient experimentation which leads to the undisputed acceptance of a novelty in practice.

In Chapter XII., On Pelvic Hæmatocele, Dr. Emmet writes: "In twenty-five years there have been but four cases of hæmatocele treated in the Woman's Hospital," etc. This is quite remarkable, as it is not infrequent in Bellevue Hospital to meet with as many cases in a single year. The picture on page 243 represents the ordinary form of pelvic hæmatocele. It is hardly possible that the tumor could have been, as the text suggests, extra-peritoneal, as extravasations of blood into cellular tissue take place slowly, and are not of great size. In the rule the bleeding takes place into the posterior cul-de-sac, or sinks there from gravity. Inflammatory adhesions form, which shut off the effused blood from the rest of the peritoneal cavity. If after the tumor has become encysted fresh hemorrhage occurs, the fluid crowds the rectum and vagina downward, and presses the uterus upward and forward against the symphysis pubis. The most favorable conditions for the rapid production of a large hæmatocele dislocating the vagina, rectum, and uterus in the manner designated, take place when old inflammatory adhesions roof over the cul-de-sac of Douglas before the effusion takes place.

The reader will naturally turn with interest to the chapters on Vesico-Vaginal Fistula. Nothing nearly so good can be found elsewhere upon the subject. The controversial portion is written in admirable temper. Heretofore we had gotten to think that there was something in the nature of the subject which was incompatible with mental serenity, or temperate discussion. When we mentioned to the late Prof. Simon that Dr. Emmet had operated some four hundred times for vesico- and recto-vaginal fistulæ, the distinguished Heidelberg professor replied, "It is not true; I have operated more times than any man living, and I have not had nearly that number." In the careful study made of the causes of vaginal fistulæ it is to be regretted that no attention has apparently been paid to the influence of pelvic contraction in the production of the lesion. A series of carefully made pelvic measurements instituted in every case would have been of incalculable value to the science of midwifery.

In its general features Dr. Emmet's book is a surprisingly good one. The style is clear though not always elegant. The arrangement of the matter is excellent. In the preface the author says: "This work is essentially a clinical digest. It includes the results of my individual experience, and aims to represent the actual state of gynecological science and art." Fortunately, Dr. Emmet's experience has been so exceptional, his industry so untiring, that the manipulation of his own material has left little room for introducing the handy-work of others, or at least of those outside his immediate circle of associates. How much of all the work that has been accomplished in gynecology dur-

ing the last fifteen years has been done in the New York State Hospital for Women, and how much of the work there accomplished falls to the credit of Dr. Emmet, can only be judged by reading the book through. It is hardly likely that a similar experience will fall to the lot of any single man in the coming generation. Gynecological methods are gradually becoming diffused and popularized. With the removal of the mystery which has surrounded the diagnosis of pelvic disorders, their treatment is destined to enter more and more into the domain of general practice. For those who are eager not only to become familiar with the higher triumphs of uterine surgery, but who are anxious as well to enter the lists and to do their part in the work, we cordially recommend Dr. Emmet's book as a capital guide, teeming with wise instruction.

Reports of Societies.

THE MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

THIRTIETH ANNUAL MEETING.

Held in Chester, May 21, 22, and 23, 1879.

WEDNESDAY, MAY 21ST.—FIRST DAY.

AFTERNOON SESSION.

The Society met, pursuant to adjournment, in Holly Tree Hall, in the city of Chester, at 3 o'clock P.M., and was called to order by Dr. Wm. B. ULRICH, of Chester, Chairman of the Committee of Arrangements. The President, Dr. JAMES L. STEWART, of Erie, Pa., took the chair.

Opening prayer was offered by the Rev. HENRY BROWN, of Chester.

The names of the delegates as registered on the book were read by the Permanent Secretary, Dr. WILLIAM B. ATKINSON.

THE ADDRESS OF WELCOME

was delivered by Dr. WILLIAM B. ULRICH on behalf of the Committee of Arrangements. He welcomed the delegates to the "old town but young city of Chester," and commented upon the manifold advantages and good results of such reunions as the present, and closed with an eloquent reference to the spirit of progress.

MISCELLANEOUS BUSINESS.

The Chairman of the Committee of Arrangements, Dr. W. B. ULRICH, reported by reading the programme of the meetings and several invitations to entertainments. These invitations were accepted and the thanks of the Society tendered.

REPORT OF CORRESPONDING SECRETARY.

Dr. OSCAR H. ALLIS, of Philadelphia, the Permanent Corresponding Secretary, then made his report, acknowledging the receipt of the Transactions of the State Medical Societies of Ohio and South Carolina. He also introduced a complaint signed by fourteen members of the Columbia County Medical Society, which was referred to a special committee to report on the next day. The committee consisted of Drs. Andrew Nebinger, of Philadelphia, Traill Green, of Easton, A. H. Halberstadt, of Pottsville, J. A. Murphy, of Wilkesbarre, and A. Thayer, of Erie. A committee on unfinished business, consisting of Drs.

Fricke, of Philadelphia, Hengst, of Philadelphia, and Orth, of Harrisburg, was also announced at the same time.

ADDRESS ON SURGERY—THE TREATMENT OF WOUNDS.

DR. CHARLES T. HUNTER, of Philadelphia, in his report, referred to the necessity of arresting hemorrhage. He was in the habit of always thoroughly wiping off a wound, and thought it was the better plan to open the wound whether the hemorrhage had stopped or whether the bleeding still continued. Where the stump was filled with clots he always made it a point to open the wound and remove all the clots. He discussed the merits of the catgut ligature, of the method by torsion of closing wounds, and of all the other ordinary methods. The catgut ligature he considered to be by all odds the best. It did not act as a foreign body in the tissues, but was either, as held by Fleming, disorganized and dissolved, or if not disorganized, its place was at least filled very soon by organized material. He wished particularly to dwell upon the value of catgut as a ligature for wounds of the larger nerves and of the tendons. The catgut, in such cases, should pass through the cellular tissue and nerve-sheath, but not through the tissue of the nerve itself. To preserve the approximation of the surfaces of wounds, it was necessary to apply compresses, and to fix the part in a splint.

Regarding drainage, he preferred to drain wounds by means of Chassaignac's (1859) tube. In closing a wound the sutures should be placed very close—not more than mm. 10-15 apart.

He was accustomed to insist upon immobility, whether the movements of the muscles were liable to disturb the approximation of the surfaces or not. The part should be placed at once upon a splint. Immobility should be maintained inviolate until the wound was fully healed, and should be assured in the very simplest wound.

The speaker believed in dry and infrequent dressing. The dressing should be light and just large enough to protect the surface. Compression of a gentle character should be always employed, but there should be no constriction for fear of obstructing the circulation. He always regarded the clinical thermometer as an excellent and most reliable index of the temperature of a wound. If the degree of temperature marked by it was under 100° F. he never allowed the dressing to be disturbed short of six days, and usually retained it in position as long as ten days. The popular idea that wounds of the face and head heal more rapidly because the parts are more vascular, Dr. Hunter said was an error; the legs and hands were just as vascular, and wounds of those parts would heal just as rapidly if they can be kept perfectly quiet.

DR. CHARLES D. NANCREDE, of Philadelphia, strongly emphasized the speaker's estimate of the catgut ligature. He believed that he was the first person in Philadelphia to use the catgut ligature and to employ the antiseptic, or Lister method. He had used the catgut ligature twice with great success in the coaptation of wounds of tendons, and had never known of any secondary hemorrhage following its employment. The wounds in which it was used had healed with wonderful rapidity. He could also bear testimony to the value of the clinical thermometer. If the scale did not at any time reach a higher point than 101° F., he was accustomed to have his residents at the Episcopal Hospital, in Philadelphia, allow the dressing to remain undisturbed.

Upon the motion of DR. BENJAMIN LEE the thanks

of the Society were tendered Dr. Hunter for his address.

SPAYING FOR SOME OF THE DISORDERS OF MENSTRUAL LIFE.

DR. W. GOODELL, of Philadelphia, spoke of the various forms of disease peculiar to the menstrual period, such as fibroid tumors, chronic ovaritis and ovariagia, prolapse of the ovaries, chronic pelvic peritonitis, ovarian epilepsy and ovarian insanity—in fact all the forms of pernicious menstruation, and referred to the great difficulty in treating them, and to the fact that they generally remained unmanageable until the change of life.

He wished to illustrate, by some cases of his own, the treatment of those conditions first proposed by Dr. Robert Battey, of Rome, Ga., who effected an artificial change of life by removing both ovaries. That operation was called "normal ovariectomy" by its originator, but he was inclined to define the operation by the good old Saxon word, "spaying." He was supported in the use of that term by such a celebrated authority as Dr. Aveling.

CASE I.—A married woman, æt. 33. This patient was scarcely ever free from pain, which came on before each menstrual period, and lasted all through menstruation, so that she passed three weeks out of every four in bed. The patient consulted Dr. S. Weir Mitchell, who called in Dr. Goodell upon the discovery of the presence of an abdominal tumor. At the time when Dr. Goodell first saw the patient she was thin, pale, and bloodless. Examination revealed an ante-flexed womb imbedded in the hilus of a kidney-shaped fibroid tumor. The sound gave a measurement of three inches. The tumor turned out to be a subperitoneal fibroid. It was determined to remove both ovaries. The operation was followed by but slight hemorrhage. Its effect was wonderful. In six months the tumor was no larger than a horse-chestnut in size. At last accounts the patient had walked four miles into the country in search of flowers.

(Dr. Goodell had collected eleven cases of spaying for fibroids besides his own, making twelve in all. In three of those death had ensued; but in those three cases the abdominal section had been made. In the remaining nine convalescence had been uninterrupted, the menopause had been established, and the tumors had decreased in size.)

He then gave the history of three cases—one successful, one death, and one in which the mental condition of the patient was not improved.

DR. GOODELL stated that he had collected statistics of 51 operations for the removal of the ovaries; out of those there had been 15 deaths. Of the 20 patients from whom the ovaries had been removed per vaginam, but 4 had died, while of the 31 cases in which abdominal section had been made, 14 had died. He always performed the vaginal operation first, and if he found it impossible to remove the ovaries through the vagina, he then made the abdominal section and used the vaginal wound as a drainage-opening. The abdominal section should always be made while the patient was lying on her side. He had no doubt that the fact that he had operated upon his third case while the woman was in the lateral position had been the cause of death. The spray should always be kept going while the abdomen was open. He had just removed a fibro-cystic tumor by incising the abdomen from the ensiform cartilage to the pubis, and the patient had recovered without a single bad symptom. Out of 132 cases collected by a European writer, there were 15 in which menstruation had continued

after both ovaries had been removed. He had no doubt that that continuance of the menses was due to the presence of a third ovary—*post-mortem* examinations often revealing the presence of one or more supernumerary ovaries. His general experience had been that the sexual appetite remained unchanged by the operation.

The paper was referred to the Committee of Publication.

Discussion being open,

DR. JOHN CURWEN, Superintendent of the State Insane Asylum at Harrisburg, remarked that Dr. Goodell's fourth case had been under his care for the past four months, and had become a continued, from being at first a paroxysmal case of insanity.

DR. ALBERT H. SMITH, of Philadelphia, regretted that Dr. Goodell had chosen such a title for his really valuable paper—using a term which was only employed in connection with the lower animals. It would be much better to preserve the title of its first advocate and call it "Batey's operation."

DR. T. J. GALLAHER suggested that obstinate cases of nymphomania might be cured by the operation in question. Might it not also be inflicted as a punishment upon prostitutes?

DR. ELLWOOD HARVEY, of Chester, did not know why male as well as female prostitutes should not be spayed.

DR. GOODELL was quite willing to accept Dr. Smith's proposal and would change the name of his paper to "Removal of the Ovaries," etc. He was not by any means sure that the operation would cure nymphomania. Drs. Spencer Wells, Atlee, and Peaslee, had all concurred in the opinion that the sexual feeling was the same, if not greater, after the ovaries had been removed.

JUVENILE INSANITY.

DR. ISAAC N. KERLIN, Superintendent of the Home for Feeble-minded Children, at Media, read a paper with the above title. Mental disease, he said, was more frequent in childhood than was commonly imagined. According to the statistics of Dr. Bouteville, the proportion of insane children, between the ages of five and nine years, was 10 per cent.; between ten and fourteen years, 35 per cent.; and between fifteen and nineteen years, 20 per cent. It was not improbable that many of the minor forms of juvenile insanity were allowed to go unrecognized, being regarded as a temporary consequence of sympathetic disturbance, or the sequel of acute disease, and so likely to pass away when the cause was removed, or overgrown. In many cases that happy sequence did not occur, and the little victims sank rapidly into the dementia of idiocy, or developed into erratic, excitable, vicious childhood, passing through the courts, and the refuges and reformatories as criminals, from whence they graduated into other planes of crime.

The paper was referred to the Committee on Publication, and the meeting was adjourned to meet at 8 P.M.

FIRST DAY—EVENING SESSION.

The Society was called to order at 8 P.M., to listen to the

PRESIDENT'S ANNUAL ADDRESS.

DR. STEWART occupied his allotted time by a brief review of the lives and characters of some of the learned and distinguished gentlemen who had presided over the Society in past years. He spoke only of those who were no longer with us, but had rested

from their labors. It was a fine sentiment advanced by Confucius that "we ought to keep the dead before our eyes and know them as if they were still living." In our eulogies and encomiums upon the great advances made in medicine, we should constantly recollect what we owe to the men of former years, who so laboriously laid the foundations upon which we were now building. Moreover, in the department of the practice of medicine, it might well be doubted if the profession, with all its improved appliances and aids, was much more successful than it was twenty-five or thirty years ago.

Dr. Stewart then referred somewhat at length to the lives of the following former presidents of the Society: Dr. Hume, of Lancaster, Dr. Heister, of Berks Co.; Dr. Carpenter of Schuylkill Co.; Dr. Cunningham, of Beaver; Drs. Concha, Jewell, and La Roche, of Philadelphia; Dr. Wallace, of Berks; and Dr. Atlee, of Philadelphia.

The Society then adjourned, to meet at 9 A.M., on Thursday morning.

THURSDAY, MAY 22D—SECOND DAY—MORNING SESSION.

The Society was called to order at 9.30 A.M., by the President. The proceedings were opened with prayer by the Rev. A. T. DOBSON, of Chester.

The reports of the county societies were referred to the Committee of Publication.

NOMINATING COMMITTEE.

The following names were read by the Secretary as members of the Nominating Committee: Drs. E. Melhorn, Adams Co.; L. De B. Kuhn, Berks; J. W. Neely, Allegheny; H. Pratt, Bucks; Jacob Price, Chester; M. F. Nelson, Mitlin; W. W. Dale, Cumberland; H. McGowan, Dauphin; Milner, Delaware; A. H. Thayer, Erie; J. W. Hughes, Indiana; B. B. Smith, Tioga; J. G. Sloan, Washington; W. S. Rowland, York; H. S. Wishart, Franklin; A. T. Palmer, Jefferson; J. M. Livingston, Lancaster; J. E. Bulkley, Luzerne; J. S. Fulmer, Northumberland; Swartz, Perry; A. H. Smith, Philadelphia; F. J. Birch, Schuylkill; Lyman, Bradford; Craig, Beaver; T. Lyon, Lycoming; S. Wolf, Montgomery; A. Gillausteller, Montone; Jas. Engleman, Northampton.

REPORT ON MEDICAL LEGISLATION.

DR. R. L. SIBBETT, of Carlisle, the Chairman of the Committee, stated that a memorial had been prepared and laid before the Legislature, now in session, requiring the registration of all practitioners of medicine and surgery by the prothonotaries of the several counties of the State. Should this bill fail to become a law, the committee requested that the members of the several county societies there represented commence registration immediately under the existing law which required the prothonotary of each county to purchase a record book, which might be called the "Medical Register" of the county.

With regard to the resolutions concerning compensation for medical experts in criminal courts, and the right to give or withhold an opinion in such courts as presented by the Lycoming County Society and referred to the committee, Dr. Sibbett said that the committee were not yet ready to touch the matter or to express any definite opinion upon a subject regarding which so much difference of opinion now existed.

The report was accepted and the committee continued.

DR. TRAILL GREEN, of Easton, said that the prothonotary of his county had procured a book and was

very willing to do the work, but had no means of forcing physicians and surgeons to register.

DR. STEWART, of Erie, the President, said that the law had been enforced in his county, and that an irregular practitioner had been arrested and had given bail, and then left the neighborhood for parts unknown.

REPORT OF THE COMMITTEE ON MEMORIALIZING THE LEGISLATURE ON FEMALE SUPERINTENDENTS FOR FEMALE DEPARTMENTS FOR STATE HOSPITALS FOR THE INSANE.

The report was read by Dr. TRAILL GREEN, a member of the committee, who said that the committee had prepared a memorial and had caused a copy to be sent to every member of the State Senate and House of Representatives; that they had also prepared and placed in the hands of the Hon. Wm. B. Roberts, representative of Montgomery County, the following bill entitled "An Act for the better regulation and treatment of the female insane in the asylums and hospitals of the Commonwealth of Pennsylvania:

"Section I.—Be it enacted by the Senate and House of Representatives of the Commonwealth of Pennsylvania in General Assembly met, and it is hereby enacted by the authority of the same: That in all hospitals or asylums now built or hereafter to be built and under control of the State, and in which male or female inmates are received for treatment, it shall be the duty of the trustees of said asylums or hospitals to appoint a female superintendent who shall be a skilful physician and who shall reside in said asylum or hospital, and who shall have the entire medical control of said female inmates.

"Section II.—That said female superintendents shall be appointed by said trustees for a term of not less than five years, and shall not be subject to removal within that term except for infidelity to the trust reposed in them, or for incompetency.

"Section III.—This act shall take effect, as to asylums and hospitals already built, in one year from the date of the passage of the bill.

"Section IV.—That all acts and parts of acts inconsistent with the provisions of this act be and are hereby repealed."

The Legislative Committee returned this bill to the house with an "affirmative recommendation," not one member dissenting. As soon as it was referred to the Judiciary Committee, the following memorial was placed in the hands of the Senate:

"To the honorable Senate and House of Representatives of the Commonwealth of Pennsylvania:

"The memorial of the undersigned members of the medical profession respectfully represents that they have learned with surprise of the introduction of a bill into the House of Representatives compelling the boards of trustees of the different State hospitals and asylums for the insane to appoint "female medical superintendents," who are "to have entire control of the female patients," and thus be independent of the chief medical officers of these institutions. Believing, as they do, that having two superintendents, acting independently of each other, in these institutions, cannot but prove detrimental to their best interests and the welfare of their patients, tending, as such an arrangement must, to destroy harmonious action, proper discipline, and good order, your memorialists trust that the bill referred to will not receive your favorable consideration. The views of your memorialists are fully confirmed by all practical experience in the management of these institutions during the last forty years, and much of the success which has

attended them has resulted from a system directly in opposition to the principles of the bill now under consideration."

This memorial, headed by the signatures of Isaac Ray, Samuel D. Gross, Thos. S. Kirkbride, D. Hayes Agnew, and J. M. Da Costa, led the Judiciary Committee to report the bill to the Senate with a "negative recommendation."

Subsequently, the Board of Managers of the State Hospital for the Insane at Harrisburg met, and, with only one dissenting vote, passed resolutions emphatically endorsing the bill as before the Senate. Robert Lamberton, Esq., of Harrisburg, legal advocate, with these resolutions in hand, and, aided by Representative Roberts, had succeeded in again putting the measure upon its feet. Thus the matter now stood.

Upon the conclusion of the report, Dr. ISAAC KIRKBRIDE, of Media, read a minority report, opposing the bill, citing the memorial of Philadelphia physicians and surgeons above quoted, and concluded with the reading of a private letter written him by Miss Dorothea L. Dix, in which that eminent philanthropist and benefactor of the insane argued against the change.

The question being open for discussion, Dr. JOHN ATLEE, of Lancaster, characterized the resolutions passed at the last meeting, creating the committee, as sprung upon the society. He was proud to say that he was the one member of the Board of Managers of the State Asylum at Harrisburg who had voted in the negative. He did not believe in two heads for an institution, but had no objection to having females appointed as assisting superintendents, provided they served an apprenticeship and got the knowledge and experience necessary for the successful treatment of the insane. He moved that the committee be discontinued, and that no further action be had in the matter.

DR. TRAILL GREEN denied utterly the imputation cast upon the inception of the movement by Dr. Atlee. He did not himself believe in a double-headed institution any more than Dr. Atlee, but the plan proposed was to have the male and female departments distinct and separate from each other, with distinct and separate superintendents. If young men who had freshly graduated from the colleges were thought competent to take charge of the insane, he did not see why the young women graduates should not be fitted to do the same thing. He himself was at first opposed to the change, but with time and reflection he had been led to believe implicitly in its necessity.

After remarks by Drs. HIRAM CORSON in the affirmative, and by Dr. S. T. DAVIS, of Lancaster, in the negative, a motion was made by Dr. ALBERT H. SMITH that the report of the majority be received and adopted as the sense of the Society. That motion was carried by a vote of 37 to 28. The minority report, upon motion of Dr. O'Neill, of Gettysburg, was referred to the Committee of Publication.

REPORT OF COMMITTEE ON EPILEPSY AND INSANITY.

DR. JOHN CURWEN, the Chairman, stated that as no statistics relative to epilepsy as a cause of insanity had been forwarded to the committee by any of the county societies, he was manifestly unable to make any report on the subject. He wished to speak very strongly, however, against the but too common practice of declaring criminals to be insane when they ought to be hung.

The speaker was supported in this position by Dr. Traill Green.

ADDRESS ON MEDICINE.

In the absence of DR. ANDREW FLEMING, of Pittsburgh, the Address on Medicine, written by him, was read by the Secretary, DR. ATKINSON. The paper was a lengthy one, and had as its title the "Symptoms, Prognosis, Diagnosis, and Treatment of Nervous or Emotional Fever."

CHOLERA INFANTUM.

DR. ELLWOOD HARVEY, of Chester, read a very interesting paper with the above title, embodying the results of a very extensive practice. The reader said that the greatest number of recoveries in cases brought under his care were the result of good nursing, where the children had been kept in cool, quiet, darkened rooms while sleeping, and had been fed with judicious care. The fatal terminations were in the homes of those who lived in one room, with the heat of a cooking-stove and its attendant odors; with the thumping of cradle-rockers on an uncarpeted floor, with glaring light; with the gabble of visitors over the sleeping child; and with all the other destructive conditions incident to such circumstances.

The first symptoms of the disease were those which pointed to some disturbance in the brain, such as clutches at the sides of the head with the hands, pulling the ears, throwing the head backward in sleeping, sleeping with the eyelids partly open and with the eyes turned upward. That was the beginning of cholera infantum, and at that stage it was easily cured by making the patient cooler, diminishing the food to an amount that could be easily digested, cutting the gums if they needed it, and, if those means were not sufficient, by blistering the scalp. The one essential cause of the disease seemed to be *excessive heat*, either of the weather or of the heated room, which might be increased in either case by too much covering over the child.

In severe attacks the speaker recommended blisters to be applied as early as possible to the denuded scalp, one on each side of the head above the ears. The plaster should be spread thick. Blisters on the scalp were slower to draw than on other parts of the body, were less painful, and healed quickly without dressing. If a crop of boils followed the blisters, there would be no more cholera infantum while they lasted. It was useful, in every case, to allow plenty of water. No treatment would succeed if the child was kept too warm. The more the patient slept the better. Always secure for it during sleep a cool, quiet, dark room, allow no talking in the room while it was asleep. When awake have it carried out in pleasant, quiet, shady places. The paper was referred to the Committee on Publication.

DR. BENJAMIN LEE said that he agreed fully with the speaker in regard to the causation of the disease. He was convinced that its sole cause was intense heat. He did not consider the disease as one of the alimentary canal, but of the nervous system. If nothing else would do good but blisters, he should not hesitate to use them, but he preferred milder measures at first, such as tepid-baths and ice to the spine.

DR. HIRAM CORSON was not much in favor of blistering. When the child was quite unconscious, he had been accustomed for a number of years to lay an ice pillow under the back of its neck.

The paper was further discussed by Drs. T. J. Gallaher and Wm. B. Ulrich.

THE DIAGNOSIS AND TREATMENT OF FRACTURES NEAR THE JOINTS.

DR. PACKARD, of Philadelphia, read a paper upon the above subject. It was almost always difficult to

determine upon the exact seat of a fracture. The existence of fractures near the joints was not often, if ever, referred to by authors. Pilcher, of Brooklyn, had published a case of a fall on the wrist where the ligaments had been strained and the bone fissured. There was, in most cases, a spot of limited tenderness over the upper ends of such fissures. Such fractures (*i. e.*, those near the joint) almost always ran in a direction which favored impaction. In dealing with all such cases, it was important to warn the patient that permanent stiffness might ensue. In treating such fractures, it was generally necessary to etherize the patient.

The paper was discussed by Drs. H. Lenox Hodge, of Philadelphia, and John Atlee, of Lancaster.

FRACTURE OF THE LOWER END OF THE RADIUS.

DR. R. J. LEVIS, of Philadelphia, made a few remarks on this subject, and exhibited a new splint for the treatment of such fractures, devised by himself, and manufactured by Mr. Gemrig, of Philadelphia.

STATE BOARD OF HEALTH.

The following was offered by DR. T. S. CRAWFORD:

"Resolved, That the Medical Society of the State of Pennsylvania, now in session at Chester, Delaware County, views with the deepest satisfaction, the progress of the Senate bill, in the House of Representatives, to create a State Board of Health. Seeing in it a promise that our great commonwealth will not long remain behind our little sister State of Delaware in establishing this much needed agency for the better protection of the lives and health of our citizens.

"Resolved, That this resolution be forwarded by telegraph to the appropriate officer of the House of Representatives."

Adopted.

THE LEGAL RESTRAINT OF HABITUAL DRUNKARDS.

The following was offered by DR. MICHAEL O'HARA, of Philadelphia:

"Resolved, That the bill now before the Legislature of this State, providing for the legal restraint of habitual drunkards in asylums especially designed for the treatment of those so unfortunately affected, commands the entire sympathy of this Society, and that we do not hesitate to urge upon the House of Representatives the duty of providing such a resource for the victims of inebriety, and the protection of their families and their property.

"Resolved, That this resolution be communicated to the proper officer of the House of Representatives at once."

Adopted.

ADVICE TO MEDICAL JOURNALS.

The following was offered by DR. GEO. HAMILTON, of Philadelphia:

"Resolved, That it is the sense of this Society that the various medical journals of this country should devote more space to general medicine and surgery, to the exclusion of extraneous matters."

Adopted.

The Society then adjourned.

SECOND DAY—AFTERNOON SESSION.

The meeting was called to order by the President, and the Secretary read an appeal by J. P. Seiler, of Dauphin County, from the decision of the censors of his district.

Upon motion of Dr. William Pepper, of Philadelphia, a committee of five members of the Society was appointed to inquire into the merits and demerits of Dr. Seiler's case, and to report upon it at the next yearly meeting of the Society.

The death of Dr. THOMPSON, of Dauphin County, being here announced, a few eulogistic remarks were made by Dr. Jno. Atlee, of Lancaster.

REPORT OF THE NOMINATING COMMITTEE.

The Committee on Nominations made the following report:

For President.—Andrew Nebinger, M.D., of Philadelphia.

For Vice-Presidents.—Wm. B. Ulrich, M.D., of Delaware County; Jacob L. Zeigler, M.D., of Lancaster County; George A. Lynn, M.D., of Washington County, and Joseph A. Murphy, M.D., of Luzerne County.

For Permanent Secretary.—Wm. B. Atkinson, M.D., of Philadelphia.

Recording Secretary.—To be chosen by the Blair County Society.

For Corresponding Secretary.—Oscar H. Allis, M.D., of Philadelphia.

For Treasurer.—Benjamin Lee, M.D., of Philadelphia.

For Committee on Publication.—Drs. Wm. B. Atkinson, Benjamin Lee, Wm. Souder, Oscar H. Allis, J. G. Stetler, and James Tyson, all of Philadelphia, and Isaac N. Kerlin, of Media.

For Delegates to the American Medical Association.—Drs. J. L. Stewart, Erie County; James Tyson, Philadelphia; J. T. Carpenter, Schuylkill; Louis Kuhn, Berks; M. F. Hudson, Mifflin; Jas. M. Sherrer, York; J. S. Crawford, Lycoming; James B. Ely, Perry; Jonathan E. Bulkley, Luzerne; Rob. B. Brown, Jefferson; Nathan McDonald, Allegheny; A. M. Miller, Lancaster; J. L. Blackley, Washington; Isaac Purcell, Montour; S. R. Rutledge, Indiana; J. R. Swigert, Snyder, Charles Stubbs, Chester; Robert Horner, Adams; Ellwood Harvey, Delaware.

For Delegates to the New Jersey Medical Society.—Drs. Oscar H. Allis, Philadelphia; J. S. Crawford, Lycoming County; George R. Welchens, Lancaster.

For Delegates to the New York State Medical Society.—Drs. A. R. Blair, York; A. Thayer, Erie; J. Ogilvie, Montour; S. S. Kosier, Schuylkill.

For Delegates to the Ohio State Medical Society.—Drs. S. A. Craig, Beaver; W. C. Evans, Erie; Geo. A. Lynn, Washington; S. Stebbins, Chester.

For Delegates to the Delaware State Medical Society.—Drs. W. W. Dale, Cumberland; R. B. Ewing, Chester.

For Delegate to the West Virginia State Medical Society.—Dr. H. G. Christman, Franklin.

For Delegates to the Maryland State Medical Society.—Drs. W. S. Rowland, York; J. W. C. O'Neill, Adams; Frank E. Mack, Schuylkill; Alexander Craig, Lancaster.

For Delegates to the Massachusetts State Medical Society.—Drs. John W. Hughes, Indiana; A. H. Halberstadt, Schuylkill.

For Delegate to the Connecticut State Medical Society.—Dr. Thomas W. Birch, Schuylkill.

For Censors for the First District.—Drs. A. Frické, Philadelphia; J. N. Kerlin, Delaware; J. Fulton, Chester.

For Censors for the Second District.—Drs. J. B. Walton, Bucks; Traill Green, Northampton; W. B. Erdmann, Lehigh.

For Censors for the Third District.—Drs. Hiram

Corson, Montgomery; W. Murray Weidmann, Berks; D. W. Bland, Schuylkill.

For Censors for the Fourth District.—Drs. Brainherd Leaman, Lancaster; H. O. Whitman, Dauphin; H. O. Orris, Perry.

For Censors for the Fifth District.—Drs. J. B. Kieffer, Cumberland; J. W. C. O'Neill, Adams; Jas. W. Kerr, York; S. G. Lane, Franklin.

For Censors for the Sixth District.—Drs. A. H. Shaeffer, Mifflin; D. P. Miller, Huntington; John Fay, Blair; J. G. Wilson, Cambria; D. S. Griffith, Bedford.

For Censors for the Seventh District.—Drs. W. S. Duncan, Fayette; D. G. McConaughy, Westmoreland; A. Anderson, Indiana.

For Censors for the Eighth District.—Drs. W. S. Forster, Allegheny; L. S. Blackley, Washington; D. S. Margin, Beaver.

For Censors for the Ninth District.—Drs. S. Graham, Butler; E. Griswold, Mercer; W. S. Welsh, Venango; J. Ross, Clarion.

For Censors for the Tenth District.—Drs. A. S. Bonsted, Erie; T. J. Young, Crawford; David Best, Crawford.

For Censors for the Eleventh District.—Drs. C. Hibler, Centre; C. K. Thompson, Tioga; Thos. Lyons, Lycoming.

For Censors for the Twelfth District.—Drs. J. D. Strawbridge, Montour; E. R. Mayer, Luzerne.

For Censors for the Thirteenth District.—Drs. D. N. Newton, Bradford; L. A. Smith, Susquehanna.

The next place and time of meeting to be the city of Altoona, on the third Wednesday of May, 1880.

THE ADDRESS ON HYGIENE.

DR. R. A. CLEEMANN, of Philadelphia, began his address with words of warning against too hasty generalizations in hygiene—as, for instance, in attributing too much to sewer-gas as a cause of typhoid fever; also as claiming too much in the prevention of disease by measures of cleanliness, without taking into consideration the exclusion of specific causes. He then spoke of the statistics of cancer as showing a vast increase in mortality from this cause, and discussed the question whether marriages should be advised between those inheriting the predisposition to this disease, deciding strongly in the negative.

Dr. Cleemann closed with a notice of the establishment of a National Board of Health, and of the progress of a bill at Harrisburg creating a State board.

EXTENSION AND FIXATION IN THE TREATMENT OF SPINAL CURVATURE, WITH A DEMONSTRATION OF THE USE OF THE POROUS FELT JACKET.

DR. BENJAMIN LEE, of Philadelphia, was introduced, and proceeded to demonstrate the great benefit derived from the application of the porous felt jacket for the treatment of spinal curvature. The great superiority of this preparation over the plaster jacket depended upon the ability of the excretions of the skin to escape through the pores in the felt material, and so conduce to the health of the patient. Dr. Lee illustrated his remarks by various drawings and crayon sketches on the blackboard.

A CLINICAL CONTRIBUTION TO EXOPHTHALMIC GOITRE.

DR. PEPPER read a very interesting clinical paper on this disease, giving the history of thirty-one cases in his practice. The ages of the patients ranged from ten to seventy years. The speaker declared the disease to be more frequent in the female than in the male, and considered it to be due in the majority of cases to anæmia, general debility, and mental anxiety.

PROFESSIONAL EXPERT EVIDENCE.

DR. JOHN H. PACKARD, of Philadelphia, made a motion that the following memorial and draft be sent to the State Legislature, after receiving the signature of all the officers and delegates of the Society: "To the Honorable, the Senate and the House of Representatives of the Commonwealth of Pennsylvania. The undersigned, members of the medical profession, practising in this State, respectfully ask the enactment by your honorable bodies of a law, a draft whereof is herewith submitted. We believe the operation of such law will be to promote the interest of citizens and the welfare of the Commonwealth."

"AN ACT TO EXTEND TO PHYSICIANS AND SURGEONS THE BENEFIT AND OBLIGATIONS OF THE LAW OF PRIVILEGED COMMUNICATIONS.

"*Be it enacted, etc.*, That no person duly authorized to practise physic or surgery shall be allowed, or compelled to disclose any information which he may have acquired in attending any patient in his professional character, and which information was necessary to enable him to prescribe for such patient as a physician, or to do any act for him as a surgeon. And your petitioners will ever pray, etc."

Adopted,

EXAMINATION OF THE USUAL SIGNS OF DISLOCATION OF THE HIP, AND AN INQUIRY INTO THE PROPER COURSE TO PURSUE WHEN THE DISLOCATION IS COMPLICATED WITH FRACTURE.

DR. OSCAR H. ALLIS, of Philadelphia, began his remarks by an examination of the usual signs of dislocation of the head of the femur. Those he took up one after the other, and demonstrated how they could be so modified as to mislead in finding the true diagnosis. "If then," said the speaker, "the signs of dislocation can vary so greatly, how great must, of necessity, be our embarrassment when fracture of the pelvis, fracture of the neck of the femur, synovitis, etc., step in to complicate the matter."

He then spoke of dislocation when complicated with fracture of the shaft, pointing out the peculiarity of a force which could first dislocate and then fracture, for he urged that those injuries could never be simultaneous. When the fracture is in the upper part of the shaft, then the dislocation had occurred first, but when the fracture occurred low down in the shaft, it would be impossible for a dislocation to occur.

In regard to the treatment, he said that he would, upon purely theoretical grounds, adapt the lower fragment to the upper, *i. e.*, if the head lay upon the dorsum ilii, he would direct the lower part of the limb across the sound one, rotating the foot inward. His remarks were profusely illustrated by chalk sketches on the blackboard.

TREASURER'S REPORT.

DR. LEE submitted his report showing that there was a balance in the treasury of \$1,067.20. After being audited by a committee appointed by the chair, the report was approved.

THE EXTERNAL TREATMENT OF SKIN DISEASES.

DR. JOHN V. SHOEMAKER, of Philadelphia, read a paper upon the above subject. He began with a description of the numerous external agents of value in the treatment of diseases of the skin. He pointed out that hard water would be found to irritate sensitive cutaneous surfaces, while sea-water actually stimulated the skin. He spoke of the chemical action of

soap, and said that medicated soap, prepared with bran, oatmeal, and borax, was decidedly beneficial. He then proceeded to discuss the use of the oleates in the treatment of diseases of the skin, as proposed by Mr. Jno. Marshall, of England. Oleic acid possessed solvent powers more active than most bases of ointments, and consequently the chemical combinations so formed were more potent when applied to the skin. Dr. Shoemaker closed with a reference to his own investigations and the combinations he had suggested, including the oleates of lead and bismuth, and described their properties and results.

The paper was referred to the Committee on Publication.

A REPORT ON THE EXAMINATION OF RAILROAD EMPLOYEES FOR COLOR BLINDNESS.

DR. PETER D. KEYSER, of Philadelphia, surgeon to Wills' Eye Hospital in that city, read a paper of particular interest, giving the result of a careful examination of the train hands on the various railroads having their terminus in Philadelphia, with regard to color blindness. He found three and one-half per cent. color blind—that is, three and one-half per cent. of the whole number who mistook colors one for the other, and eight and one-half per cent. additional, who, although able to distinguish the colors, were unable to tell the shades, *i. e.*, who shaded badly, thus making twelve per cent. of those examined who are not quick and sharp in noticing and distinguishing colors and shades. The three and one-half per cent. had visual defects of such a character as to make them really incapable and unsafe to fill the positions which they occupied. The speaker's attention was mainly attracted to two peculiarities. One was the fact that two men, who could not distinguish red from green on test, had educated themselves to know that red was an intense color, and were thus able to distinguish bright red signals, but at the same time bright green and other bright colors were red to them. For those they said that they would stop the trains, thus being on the safe side and never having an accident to occur to them. But dark green they called a deep, or dull color, and dark red, dark green, and brown were all green to them, and they would pass them by as all right on the road, thus causing them to be unreliable in their positions. The other peculiarity was the power of distinguishing bright red when held within three feet of the eyes, while at ten, twenty, and thirty feet, it was invariably called green. In sorting the wools, bright red and light green he picked out together for red. In that case the acuity of vision was normal.

The paper was accepted and referred to the Committee on Publication.

The Society then adjourned.

In the evening a reception was tendered to the visiting delegates by the Delaware County Medical Society, at Holly Tree Hall, from 8.30 to 12 P.M.

FRIDAY, MAY 23D—THIRD DAY—FINAL SESSION.

The delegation left Chester by a special train at 8.30 A.M., for the Institution for Feeble-minded Children, at Media, where the closing session was held.

The Society was called to order in the main hall of the institution at 9 A.M., by President Stewart.

Appointments.

The following gentlemen were appointed to prepare papers to be read at the next annual meeting:

Address on Medicine, Dr. Thomas W. Shaw, of Pittsburgh.

Address in Obstetrics, Dr. J. T. Carpenter, of Pottsville.

Address in Surgery, Dr. John H. Packard, of Philadelphia.

Address on Mental Disorders, Dr. Isaac N. Kerlin, of Media.

Address in Hygiene, Dr. Benjamin Lee, of Philadelphia.

A letter was then read from Dr. James A. Reed, of Allegheny County, saying that he had been prevented by illness from writing the address on mental disorders for the current year.

REPORT ON STATE BOARD OF HEALTH.

DR. BENJAMIN LEE, of Philadelphia, read the report, which stated that the committee had addressed a memorial to the Legislature, urging the passage of the bill reported by the State Society, and that they had personally visited Harrisburg for the purpose of impressing upon the members of the Legislature the great importance of the measure. In the meantime another bill, on the same subject, had been introduced into the Senate, which the committee supported as amended at their suggestion. One of the valuable features in the bill which had passed the Senate and was now pending a second reading in the House, was that it introduces county boards of health. The doctor also stated that the act had reached a further stage than any previous one for the same purpose.

The report was received and the committee continued until the final action on the bill was decided.

NOCTURNAL EPILEPSY.} |

DR. JOHN CURWEN, of Harrisburg, read a paper on this subject, translated from a French work, which was referred to the Committee on Publication.

HOMES FOR INEBRIATES.

DR. JOSEPH PARRISH, of Burlington, delivered a very interesting address upon this subject, and reviewed the various systems in this country and Europe. It was referred to the Committee on Publication.

A recess was then taken in order to give an opportunity to Dr. Kerlin, the Superintendent of the Institution to introduce the inmates on the stage. This was done, and the classes went through gymnastic exercises. Dr. Kerlin then made a few remarks and introduced Dr. Seguin, Sr., to the society. Dr. Seguin spoke on the subject of Kindergartens.

METHODS OF EXCISING THE UPPER JAW FOR CANCER.

DR. WILLIAM H. PASCOAST, of Philadelphia, spoke at some length on this subject.

ADDRESS OF THE RETIRING PRESIDENT.

DR. STEWART, in retiring, thanked the Society for the kindness and courtesy extended to him while in the President's chair.

ADDRESS OF THE PRESIDENT ELECT.

DR. STEWART then introduced Dr. Andrew Nebinger, of Philadelphia, the President elect, who thanked the Society for the honor it had conferred upon him, congratulated the members upon the prevailing harmony and good fellowship, and asked their support in the discharge of his duties.

Resolutions were then adopted endorsing the Pennsylvania Institution for Feeble-minded Children, recognizing the ability of the Superintendent, Dr. Isaac Kerlin, and thanking that gentleman and the Board of Managers for their courtesy.

The resolutions were seconded warmly by Drs. Stewart, of Erie, Ellwood Harvey, of Chester, and

Nebinger and Shoemaker, of Philadelphia. The Society then adjourned, to meet at Altoona on the third Wednesday of May, 1880. At the conclusion of the meeting the members of the Society were entertained by Dr. Kerlin.

On Saturday morning, at the invitation of the officers of the Camden and Atlantic Railroad, the delegates made an excursion to Atlantic City.

Correspondence.

KENTUCKY THE FIRST STATE OF THE UNION IN WHICH ANÆSTHESIA WAS EMPLOYED IN THE OPERATION OF OVIARIOTOMY.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—From reading the various interesting reports of the proceedings of the State Medical Society of Kentucky, which met at Danville, May 13th, to erect a monument to the memory of Ephraim McDowell, the first ovariologist, I find no mention or allusion, not even in the masterly oration of Dr. Gross on the occasion, to a somewhat important event in the Kentucky history of this operation. I refer to the first employment of anæsthesia, which has contributed so largely, not only in our own country, but throughout the civilized world, towards perfecting the operation of ovariotomy, and leading to the brilliant results now embalmed in the hearts of hundreds of living women who would to-day be in their graves had it not been for the inestimable advantages of this agent. In a conversation last evening with my friend Dr. L. A. Sayre, President-elect of the American Medical Association, who was present at the Danville ceremonies, he informed me that no allusion was made by any one, on the occasion, to the circumstance of Kentucky being the first State to lead off in this operation with the use of anæsthetics; and this is my reason for trespassing on your kindness for a corner in your columns to present a few facts bearing upon the subject.

In October, 1846, sulphuric ether, or lætheon, as then called, was first employed as a pain-destroyer in a surgical operation by Dr. Warren, of Boston. Only one operation of ovariotomy in this country was performed during this year, which was by Dr. John L. Atlee, before the date above given. In 1847 Dr. Robert Thompson performed the only operation for that year; but no mention is made of the fact that lætheon was employed. Both operations successful. In November, 1847, Prof. Simpson, of Edinburgh, employed, for the first time, chloroform as an anæsthetic. On March 15, 1848, Dr. Clay, of Manchester, England, performed his first ovariotomy under the influence of chloroform—successful. On March 21st, six days afterwards, Mr. H. G. Potter, of Newcastle, performed a similar operation under the influence of chloroform—unsuccessful. On April 6th, sixteen days later, Dr. Henry Miller, of Louisville, Ky., performed in that city ovariotomy under the influence of chloroform, upon a woman from the State of Indiana—successful—second case in the world under anæsthesia. During this year there were three other ovariotomies performed in this country, though they were after Dr. Miller's. Only one of the three successful.

Now, owing to the shortness of the time between Dr. Clay's operation and that of Dr. Miller—twenty-

two days—and the great distance, with the Atlantic intervening, it was not possible at that date that there could have been any communication between these two surgeons as to the advantages to be derived from anesthesia in the operation; and the inference is, that the latter acted entirely upon his own judgment in deciding to employ the agent, which had not been done before in this country.

Kentucky, therefore, in weaving her chaplet of laurels from the justly great operation inaugurated by the bold and fearless hand of McDowell, might have added to it also the one of Prof. Henry Miller, who, to say the least of him, was among the ablest contributors to the revival of the operation, and, as such, his memory is deserving of the highest recognition. The teachings of this able and good man still have a strong hold on the affections of his numerous pupils scattered throughout our broad country; and, as one of the number, I insist upon his claim to originality and superior judgment, as being the first to employ in his own country anesthesia in the operation of ovariectomy.

The failure of Dr. Gross to mention the name of Prof. Miller in this connection, in his otherwise able and just review of the labors of other cultivators of the operation of ovariectomy since it was given to the world by Dr. McDowell, was due, no doubt, to an oversight of the dates above given, and not from any disposition to be unjust, as everybody knows.

The writer, at the time of Prof. Miller's operation, was a private pupil of Dr. Gross, and had been in the habit, almost daily, of administering for him chloroform in his operations; and it was from this circumstance that Prof. Miller invited him to give the anæsthetic to the patient in question, to which incident in the American history of ovariectomy he refers here with no little pride.

Very truly yours,

NATHAN BOZEMAN.

296 FIFTH AVENUE, May 27, 1879.

A REPLY TO "NONNE."

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—In your journal for May 3, 1879, appeared a letter, signed "Nonne," which directed the attention of the Committee of Ethics for the Medical Society of the County of New York, to certain alleged irregularities, and expressed the query, "Is that Committee dead?" etc. The Committee has waited patiently until the present date for either "Nonne," or any one who may feel himself seriously aggrieved, to prefer charges against any offender, and if needs be to instruct them how to act upon the question. The Committee is alive and prepared to do their duty, their whole duty, and nothing but their duty. Now that "Nonne" has not appeared, the Committee is willing to say that they are fully impressed with the belief that when a work is published, be it medical or otherwise, it becomes the property of the public, and as such, is subject to criticism by the press. If the editor is fortunate enough to gain a favorable report for his journal or his book, we do not consider him a subject of discipline by the Committee on Ethics.

If "Nonne," however, will present charges against the gentleman in question, and is prepared to substantiate the same, he will find the Committee on Ethics ready conscientiously to do their legitimate work.

"Nonne" has a right to his own views on this subject most assuredly, and if he desires to know whether

a committee that has always endeavored to discharge its duty, is dead or living, let him prefer charges over his own signature, and a satisfactory answer can be immediately given.

Yours respectfully,

R. A. BARRY, M.D.,

Chairman Committee Ethics.

June 2, 1879.

Obituary.

JACOB A. WOOD, M.D.,

DIED at his residence, 45 Lafayette Place, New York city, on the 21st of March, 1879. His death was caused by organic disease of the heart, from which he had suffered for some time.

Dr. Wood was born in Hancock, N. H., May 10, 1810. He studied medicine with Dr. Twitchell, of Keene, N. H., and received his diploma from the Vermont Medical College (Woodstock).

After graduating, he practised for a few years in his native town. Subsequently he went to Boston, and while there began to give special attention to the treatment of Pott's disease. His reputation in that department soon became widely extended. He came to New York in 1858, since which time his brace has become quite generally known.

Dr. Wood was unpretending, and was eminently successful in his profession. He was a devoted friend and a true gentleman, and died greatly mourned by all who knew him well. At about the time of his death he was elected to membership in the Medical Society of the County of New York.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from May 25 to May 31, 1879.

SURGEONS C. T. ALEXANDER and D. L. HUNTINGTON, and Asst. Surgeon H. LIPPINCOTT, appointed a board to assemble June 2d inst., at Military Academy, West Point, N. Y., for examination of physical qualifications of members of graduating class and of candidates for admission to Military Academy. S. O. 122, A. G. O., May 23, 1879.

STORROW, S. A., Major and Surgeon, relieved from duty at Fort Laramie, and assigned to duty as Post-Surgeon at Fort D. A. Russell, Wyoming Ter., relieving Major J. R. Gibson, Surgeon. S. O. 45, Dept. of the Platte, May 26, 1879.

O'REILLY, R. M., Capt. and Asst. Surgeon, McPherson Barracks, Atlanta, Ga. Granted leave of absence for one month, with permission to apply for an extension of one month. S. O. 84, Dept. of the South, May 28, 1879.

DE WITT, C., Capt. and Asst. Surgeon. Relieved from duty at Fort Fred. Steele, Wyoming Ter., and assigned to duty as Post-Surgeon at Fort Sidney, Nebraska, relieving Capt. C. E. Munn, Asst. Surgeon. S. O. 45, C. S., Dept. of the Platte.

LA GARDE, L. A., 1st Lieut. and Asst. Surgeon. Having reported in person at these headquarters pursuant to orders from Headquarters of the Army, assigned to duty at Cantonment on North Fork of Canadian River, Indian Ter. S. O. 101, Dept. of the Missouri, May 23, 1879.

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT.—Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending May 31, 1879.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.

JOHN TAYLOR CROOK, M.D.—At a meeting of the San Francisco Medical Benevolent Society, held May 21, 1879, the death of Dr. John T. Crook, late Secretary of the Society, was announced, and the following resolutions adopted:

Whereas, It has pleased our Heavenly Father to remove from among us, by death, our friend and fellow-member, John Taylor Crook, M.D., late Secretary of this Society; be it

Resolved, That we desire, as individuals and as a Society, to place on record our appreciation of the life and character of our deceased brother; that we call to mind with gratitude his labors as an officer of our association, and our regret at his untimely death.

Resolved, That our heartfelt sympathy is hereby tendered to the bereaved father and sister, as well as to the orphaned children, too young to fully appreciate their loss.

Resolved, That these resolutions be spread upon the minutes, and a copy of the same sent to the father of our deceased member. Also that they be published in the *Western Lancet* and the New York *MEDICAL RECORD*.

BENJAMIN R. SWANS, M.D.,
 GEORGE H. POWERS, M.D., } *Committee.*
 A. F. SAWYER, M.D.,

Attest: A.M. Wilder, M.D., *Secretary.*

ARKANSAS STATE MEDICAL SOCIETY.—STATE BOARD OF HEALTH.—At the Annual Meeting of the Arkansas State Medical Society, held at Little Rock, May 14 and 15, 1879, the portion of the President's address referring to a State Board of Health was referred to a committee, consisting of Drs. J. M. Keller, P. O. Hooper, W. B. Welch, D. A. Linthicum, and E. T. Dale. After careful consideration, the committee reported the following resolutions:

Resolved, That the President of the Society appoint nine members of the same, who shall act in the capacity of a State Board of Health as far as practicable, and under the sanction and co-operation of the State government.

Resolved, That said committee or State Board of Health shall organize by the election of a president and secretary, and shall endeavor to secure membership in the Mississippi Valley Inter-State Sanitary Commission on the same footing as the State Boards of Health.

Pursuant to the foregoing resolutions, the President appointed as said board Drs. E. R. Du Val, Fort Smith; J. B. Cummings, Forest City; W. M. Lawrence, Batesville; E. T. Dale, Texarkana; D. A. Linthicum, Helena; J. A. Dibrell, Jr., Little Rock; A. L.

Breysacher, Little Rock; J. T. Hamilton, Pine Bluff; and L. P. Gibson, Little Rock.

On motion of Dr. Welsh, the President, Dr. A. A. Horner, was added to the State Board of Health.

The committee, representing a State Board of Health, immediately organized by the election of Dr. A. L. Breysacher, President, and Dr. J. A. Dibrell, Secretary.

PHILADELPHIA ACADEMY OF SURGERY.—A movement has been for some time past in progress among the well-known surgeons of Philadelphia, such as Professors S. D. Gross, D. Hayes Agnew, and Jno. Ashhurst, Jr., looking towards the foundation of a society for the reading of papers on, and discussion of, surgical matters. After several informal meetings at one another's houses, it has been decided to hold a business meeting early in June, at which a constitution may be drawn up and officers elected. It is proposed to put the "Academy of Surgery" on a similar footing with the "College of Physicians" of Philadelphia. The project has our best hopes for its ultimate success.

PRELIMINARY MEDICAL EXAMINATIONS IN THE UNIVERSITY OF PENNSYLVANIA.—The last edition of the Catalogue of the Medical Department, that for May, 1879, contains the following interesting announcement: *For entrance at the coming session (1879-80) no preliminary examination will be required, but in the fall of 1880 (session of 1880-81) a preliminary examination will be instituted, which every candidate, who has not previously received a collegiate degree, must pass.* The applicant will be required: *first*, to write a brief essay, not exceeding a page of foolscap, which will serve as a test of his qualifications in orthography and grammar; *second*, to undergo an examination in the elementary principles of physics, as contained in Fownes's Chemistry; *third*, to pass an examination in easy Latin prose translation (*First Book of Caesar's Commentaries*). In lieu of Latin, any language other than English may be substituted.

THE second series of the Mütter Foundation Lectures for 1879 (surgical pathology) is now in course of delivery at the Philadelphia College of Physicians. The lecturer, Dr. Samuel W. Gross, delivered the first two lectures on Tuesday and Friday evenings, May 27th and 30th. The last two will be delivered on June 3d and 6th. The subject of this second course is: The Histology, Genesis, Pathology, Differential Diagnosis, and Treatment of Fibromas, Sarcomas, Myxomas, Adenomas, and Carcinomas of the Breast. The entire series, first and second (ten lectures in all), will be published in the form of a monograph at an early date by the author.

INHALATIONS IN THE TREATMENT OF PULMONARY DISEASES.—In that form and stage of chronic bronchitis characterized by an excessive purulent or mucopurulent expectoration, an inhalation of steam impregnated with the vapor of carbolic acid and camph. tincture of opium will be found to afford prompt relief to all of the immediate symptoms, the carbolic acid acting as an antiseptic, while the moist warmth and the opiates allay local irritation and the resulting cough. The formula which I am in the habit of using is as follows:

B. Acid carbolic, cryst. grs. xxx.
 Tr. opii et camph. ℥ij.

M. Sig.: One teaspoonful in half a pint of hot water, to inhale as directed.

Another stage of chronic bronchitis is distinguished

by a harsh, hard, irritative cough, and little or no expectoration. Such portions of the respiratory mucous membrane as can be brought within view present a pale, anæmic, and dry shrivelled appearance. Here we require, locally, a combination calculated to stimulate free capillary circulation and secretion, and also to exert the soothing anodyne influence necessary to control cough. For this purpose we have found the following combination to answer exceedingly well:

R. Oil of Scotch pine..... ʒj.
 Camph. tinct. of opium..... ʒiij.

M. Sig.: One teaspoonful in half a pint of hot water, to inhale as before.

For the oil of Scotch pine almost any of the oleo-resin, balsamic preparations may be substituted.—F. H. Davis, M.D., Chicago, Ill., in *Detroit Lancet*, May, 1879.

COLLEGE OF PHYSICIANS AND SURGEONS.—The changes in the Faculty at the College of Physicians and Surgeons, Med. Dept. of Columbia College, are as follows: Dr. Henry B. Sands has been associated with Dr. Thomas M. Markoe in the chair of Surgery, Dr. Markoe assuming the title of Professor of the Principles of Surgery, and Dr. Sands assuming the title of Professor of the Practice of Surgery. Drs. T. Gaillard Thomas and James W. McLane, lately styled Professor and Adjunct Professor, respectively, of Obstetrics and the Diseases of Women and Children, have assumed the titles—Dr. Thomas, of Professor of Gynecology, and Dr. McLane of Professor of Obstetrics and the Diseases of Children. Dr. Thomas T. Sabine, lately Adjunct Professor of Anatomy, has been appointed Professor of Anatomy, vice Dr. H. B. Sands, resigned; and Dr. William T. Bull has been appointed Assistant Demonstrator of Anatomy, vice Dr. Charles Kelsey, resigned.

CEREBRO-SPINAL MENINGITIS.—Dr. J. H. Stranher, of Lexington, Mo., writes that Dr. Lee Alexander, of Marshall, Mo., treated cerebro-spinal meningitis as follows, with great success: Resolved to try something, as all previous plans had proved unavailing, the patient's body was entirely anointed with oil of turpentine; and then, with the exception of the head, to which ice was applied, he was immersed in a barrel of water as hot as could be borne by the hand. The bath was continued for fifteen minutes, and repeated every hour until relief came to the patient, which was usually so marked that for the second bath it became necessary to arouse him. The tetanic symptoms were usually relieved by the first immersion, and subsequently the bath was called for by the patient. The internal treatment consisted of turpentine in 15-25 drop doses, bromide of potassium 15-20 grain doses, gelsemium, beginning with doses of 8 to 10 drops, and increasing until double vision occurred, and blister to the nape of the neck. He claims twenty-two recoveries out of twenty-three cases. The only untoward symptom developed during treatment was epistaxis in a child two years old, which subsided as soon as the gelsemium was discontinued, it having resisted all the usual remedies.

THE USE OF CALCIUM SULPHIDE IN THE TREATMENT OF INFLAMMATIONS OF THE EXTERNAL AUDITORY MEATUS.—Dr. Samuel Sexton, in a paper published in the January (1879) number of the *American Journal of Otology*, gives his own observations on the use of this drug in the painful affections alluded to. Dr. Sexton states that in furuncular inflammation of the meatus the sulphide can be used to advantage when suppuration threatens, or even after it has occurred.

He has frequently observed furuncles, under the use of this remedy, to abort and dry up without discharge of pus. In some instances he relies entirely on the remedy in the treatment of inflammation of the ear. The prevention of a continuance or a return of furuncles, etc., by this remedy he regards as very clearly possible, provided no remote cause be left. The dose which Dr. Sexton has found most available is one-tenth of a grain, to be given every two or three hours in urgent cases. In cases with a tendency to chronicity, with less frequency. In children the dose should be less; an adult dose being diffused in water, the amount given can be easily graduated. The medicine is more agreeable when triturated with sugar of milk, when it may be given dry on the tongue.

DENTISTS IN HOLLAND.—Up to the present time only physicians provided with diplomas have been allowed to exercise the art of dentistry in Holland, but a law was recently passed which does away with this excessive restriction, while it at the same time secures sufficient guarantees for the public safety. The aspirants for the diploma of dentist, under the new law, must pass a special examination in the anatomy and physiology of the teeth, gums, and alveolar processes, on the local remedies in use for diseases of the teeth, and in operative dentistry and the preparation of false teeth. The illegal exercise of the art of dentistry is punished by a fine of from \$12.50 to \$50.00, and imprisonment for one to six months. These penalties will also be inflicted on any dentists who employ anaesthetics, such as chloroform and nitrous oxide, or who prescribe internal remedies, as well as on those who attempt to sell any drugs, except ordinary dentifrices.

THE MASSACHUSETTS STATE MEDICAL SOCIETY holds its annual meeting in Horticultural Hall, Boston, June 10th and 11th.

THE MAINE STATE MEDICAL SOCIETY holds its annual meeting in the city of Portland, beginning June 10th.

ADULT CHOREA—SYPHILITIC BRAIN DISEASE—BRAIN TUMOR.

A CLINICAL LECTURE DELIVERED AT CHARITY HOSPITAL,

By A. McLANE HAMILTON, M.D.,

VISITING PHYSICIAN TO THE HOSPITAL FOR EPILEPTICS AND PARALYTIKS.

LECTURE IV.

(Reported for THE MEDICAL RECORD.)

GENTLEMEN:—The contortions and grimaces displayed by the woman before you are certainly suggestive of an intensely dramatic and eccentric nervous disease, and among the disorders of motility, chorea occupies a prominent and interesting place. Our first patient is a middle-aged woman who, eight or ten years ago, and without any special cause, unless mental excitement and previous grief may be assigned as such, developed a disease which is rare in adults, but very common in infancy.

She has been under observation for the last six or seven years, and during that time her disease has undergone various modifications. At one time the movements were completely extinguished and recovery was supposed to have taken place. She now has peculiar contortions of the face, shown mostly about the mouth, which is puckered spasmodically, and she seems to forcibly smack her lips. On account of this embarrassment of movement she is entirely unable to talk, stammering and spasmodically uttering her words in a manner almost unintelligible. Her right arm, you will notice, is moved in irregular way, there being present a condition which is symptomatized by clonic spasms. Her right hand is swayed backward and forward, the movements of flexion being much more marked and decided than those of extension.

There is considerable loss of power on the right side, but there is no disturbance of sensation. Her general health is apparently unaffected.

On auscultation no cardiac murmur can be detected; such murmurs, as you already know, being very commonly present in cases of infantile chorea. This case differs in many respects from chorea ordinarily seen in general practice. Adult chorea, beginning late in life, is quite rare, and differs very decidedly in its pathology from that of early life. In childhood there is a superabundance of nerve-force, which, as a rule, in the normal state, finds expression in muscular movements connected with emotional exhilaration within moderate limits. But if there be slight departure from the normal condition to a state of irritability of the nervous centres, such irritability is attended by uneven discharge of nerve-force, and a pathological condition of motility often grows insensibly out of what may have been in the beginning simply a physiological one. In the chorea, then, which occurs after the age of twenty, unless the disease be hysterical or epidemic, we should always suspect the presence of organic nervous disease, especially of the cortex cerebri.

It was only a few weeks ago that a woman, who was well known to many of the visitors of the hospital, died after being affected with the disease for twenty or thirty years. Her movements were somewhat like those presented in the patient before you, but much more violent. Her arms were forcibly ex-

tended, her fingers were interlocked, her body was bent over, her head was agitated chiefly by the muscles of the anterior part of the neck. While she was kept in a state of constant agitation, her fingers were interlocked, she threw her arms about violently, doing injury to herself and to those about her. Treatment had been of no effect whatever, and, from a condition of apparent general health and fair intelligence, she descended until she became completely demented. After death, the convolutions on either side of the fissure of Rolando were found to be atrophied and the seat of sclerosis, while spots of sclerosis were scattered through the motor tract of the entire brain. In most of these cases such cortical changes will probably be found.

Another class of rare cases of chorea are those connected with pregnancy, and here the disease usually disappears before parturition. Jaccoud considers this form of chorea to be an unusually grave one, but such has not been my experience. In several cases that have come under my observation, the women have gone to full term and given birth to healthy children.

It is rare for the chorea of infancy to continue after the twentieth or twenty-fifth year. A few such cases may be seen, but when they are encountered, I am convinced that the disease is not the ordinary form which occurs among children, but rather one of a symptomatic nature.

Sometimes you will find a variety of chorea which appears in girls at about the time of puberty. It is decidedly hysterical in character, is associated with menstrual disorder, ovarian tenderness, and decided emotional disturbances. Under appropriate treatment it disappears in a very short time, and rarely recurs, though in some of the extraordinary cases reported by Continental writers, chorea may be a feature of hysterical epilepsy. The form of which I spoke in a previous lecture is interesting in a diagnostic point of view, but confusion need but rarely occur, as it is always preceded by hemiplegia or some form of paralytic seizure.

In this case, arsenic, strychnia, and more lately the dracontium, as recommended by Wood, have been given with no good results whatever, but from the persistence of her symptoms, I am convinced the condition has long passed the stage which might be called functional disturbance.

SYPHILITIC BRAIN DISEASE.

Here, gentlemen, is a patient who has just entered the hospital. She is probably between fifty and sixty years of age. It is impossible to get from her any history, as her mind, evidently, is decidedly impaired, and she appears stupid and dazed by her new surroundings. Let us examine her motility. You will observe that there is right facial paralysis; that the left corner of her mouth is drawn up; and that her tongue, when protruded, points to the right side. You will also notice that her pupils are unequally dilated, the right being very much smaller than the left; in fact, the right pupil is unusually small.

Her left side, you will observe, is the seat of hemiplegia which is not very profound, but it is probably of long standing, for there is rigid flexion of the forearm, and decided rigidity and tension of the tendon of the biceps, showing that secondary degeneration has taken place. As we examine the right side we also find that it, to a certain degree, is rigid, and the tendon reflex may be very easily produced. In fact, the tendon reflex is pretty generally exaggerated, for when Dr. Claddek strikes any of the tendons there is a violent movement. This has been found to exist

in hemiplegic cases most markedly upon the paralyzed side. In this patient it exists to some degree upon both sides, showing that the lesion is either a double one or affects some locality producing bilateral trouble.

When she attempts to answer my questions it is to be noticed that her speech is decidedly affected, the labials being badly pronounced. As a cause for this, you will observe that there is some ataxia, especially in the movements of the lips. No history has come with her, consequently it will be necessary for us to carefully examine for any indications of a predisposing cause. They are present. Upon the left side of her head there is a bald spot, the result of alopecia areata. As we examine the skin we find cicatrices, some of them over the back and the breast, but the greater number upon the anterior aspect of the legs. Irregular elevations along the course of the tibiae suggest the existence of nodes. There is, therefore, but little need of searching farther for the probable cause of the condition from which she is suffering. Her trouble, doubtless, has a syphilitic origin. Our suspicions are strengthened very much by the appearance and the grouping of the symptoms. Irregular paralysis, headache, unequal dilatation of the pupils, ataxic speech, and the chronicity of the attack, all go to confirm the diagnosis.

You will find in practice that irregular paralysis of the cranial nerves, mental decay of the kind found in this case, and rapidity in the expression of symptoms, usually point to syphilitic neuroses.

From the peculiar speech involvement, the bilateral trouble, and the uneven contraction of the pupils, it is probable that there is a lesion at the posterior and basal part of the brain as well as others more anteriorly. The condition of the patient's mind is very suggestive of cortical disease, the vertical gray matter often being affected in brain syphilis.

We shall first endeavor to improve the patient's general condition, for she has evidently been neglected. After this I shall administer the "mixed treatment," which is better than any other in these cases.

Now, here is another case of syphilitic disease of the brain, which is very interesting. It is a case of alternating hemiplegia, the patient having had attacks of hemiplegia at different times on both sides, there being a slow development of the paralysis and some amelioration before the occurrence of the second attack. In this case there is aphonia, apparently of central origin, but there is no local ulceration of the vocal cord. It has improved somewhat under specific treatment, as has her paralysis, which you see is irregular. This woman's eyes present the evidences of old iritis, which it is not difficult to detect in such patients.

The peculiarity of all of these cases is, that the symptoms are very likely to undergo a remarkably rapid alteration in character. Spontaneous changes seem to occur, and are undoubtedly due to deposits which are partially absorbed, or endoarteritis of irregular course. As a rule, syphilis attacks the dura mater and convexity of the brain, and is in nine cases out of ten the cause of the monoplegias; and is rarely unaccompanied by mental decay. In both of these patients the cerebral syphilis did not appear until eight or ten years after the primary sore. Fournier fixes the limit for the development of brain syphilis between the third and twenty-eighth years after infection, but I think symptoms of cerebral trouble are very rarely expressed until after at least eight or ten years. If the patient be not taken in hand at once the prognosis is bad, and I have found that in por-

tion to the degree of mental trouble, so will the unfavorable character of the prognosis depend.

BRAIN TUMOR.

The next patient I will present is one of a kind which puzzles the neurologist more than almost any other, and diagnosis is certainly always difficult, and sometimes impossible. She is, as you see, a middle-aged woman, and the chief features of her case are convulsions of an epileptic character, a certain amount of muscular weakness in the lower extremities, occasional variations of hyperæsthesia, and double optic neuritis. These symptoms were manifested slowly; convulsions appearing first. Soon after their onset she began to suffer from loss of vision, and for the last three years she has been entirely blind. When her eyes were examined with the ophthalmoscope it was found that marked retinal change had taken place. The veins were distended and irregular in their course, while the optic discs had lost their character, had changed in color, becoming pale, while at certain points the evidence of hemorrhage is very perceptible. This woman's pupils undergo decided variation in size, but they are usually widely dilated. She complains of intense headache, more severe upon the left than upon the right side, and she suffers quite frequently from distressing vertigo. Her taste and smell are very decidedly impaired, and although ammonia produces lachrymation, it does not always cause distress. She cannot distinguish pepper, although she feels the prickling on the tongue after its application. She is deaf in the right ear. Her convulsions are not so frequent as they formerly were. They have sometimes occurred without loss of consciousness, and are always decidedly irregular in character. From all the evidences in this case, from the optic neuritis, which may, but rarely does occur from upper brain tumors, from the deafness, and from the staggering gait, it is very probable that she is suffering from a tumor which is situated at the base of the brain. The convulsions, the optic neuritis, the headache, the cranial nerve paralysis, and one other symptom from which our patient has not suffered, namely, cerebral vomiting—all point very strongly to tumor of the brain, although it is somewhat difficult to make out its exact location. According to the recent investigation of Ferrier and others, loss of smell and hearing follow destruction of the temporo-sphenoidal convolutions, and it is very probable that such is the situation of the lesion in this case.

ANTISEPTIC TREATMENT OF THE GENITAL CANAL IN WOMEN.—The following is Schuecking's method of procedure: Immediately after delivery he wipes out the vagina with a tampon of cotton dipped in a five per cent. solution of carbolic acid; after this he carries up to the fundus of the uterus a uterine sound enveloped in gauze previously soaked in the same solution. Then, by means of an irrigator, which is connected with the uterine sound, the uterus and the vagina are thoroughly disinfected. He finally fills the irrigator with a solution containing 10 per cent. of the sulphite of soda, and 5 per cent. of glycerine; this is destined for permanent irrigation. Every twelve hours he removes the sound with the gauze enveloping it, and replaces it by another sound prepared in the same way. At the same time he repeats the carbolic acid injection, and follows it as before with the soda solution. The duration of the treatment varies according to the necessities of each particular case.—*Gazette Obstétricale.*

NERVOUS DISEASES CONNECTED WITH THE MALE GENITAL FUNCTION.

By GEORGE M. BEARD, M.D.

(Continued from No. 4, page 73, January 25, 1873.)

II.

WHEN ARE INVOLUNTARY SEMINAL EMISSIONS PATHOLOGICAL?

That this question is one of great difficulty and of great importance in its relations to the nervous system, will be denied only by those who have not given it careful thought and study. The exhaustive and independent investigation of even a few cases of nervous disease, complicated with seminal emissions, suffices to prove the inadequacy of all attempts to solve the problem through any arithmetical formula; to say, as the authorities do, that an emission two or three times a week is physiological—that is neither a result or cause of disease—is to make a statement that is not supported by verifiable facts, for emissions even less frequent are certainly both the results and causes of nervous morbid symptoms, and are therefore as truly pathological as too frequent urination or defecation.

It may perhaps be possible to move in the direction of the truth on this subject, even if we do not quite reach it by the following analysis:

INVOLUNTARY EMISSIONS ARE PATHOLOGICAL.—THAT IS, CAUSES OR RESULTS OF DISEASE.

1st. When they are followed by headache, languor, depression, nervousness, and pain, local or general.

That such morbid nervous symptoms do result directly and solely from involuntary emissions, entirely independent of the fear or expectation of the patient, is as demonstrable as that such symptoms follow excessive physical or mental exertion; for all of these sufferers are not, as is currently supposed, and often stated, hypochondriacs; many of them are as calm and as philosophical as patients of any other class.

Hypochondria, although a very frequent accompaniment of these disorders, is not essential to them in all stages; and in some cases is not found at any stage.

Even in the married, these effects of involuntary emissions are noticed; and, besides other symptoms of nervous disease that happen to be present, are liable to be aggravated after occasional emissions. These nervous symptoms sometimes appear when the emissions are quite infrequent, while in other cases they are not observed when several discharges occur monthly. There can, indeed, be no mathematical law that will apply to all cases. What is physiological—that is, consistent with average health—neither a result or effect of disease—may be another pathological; consequently, each case must be studied by itself. In some cases involuntary emission, like coitus, is followed by a feeling of relief and healthful sedation. One of my cases, long troubled with symptoms of sexual neurasthenia, is always very much better for several days after an emission, which occurs but occasionally.

2d. When, after long intervals, they occur several times a night, or a number of nights in succession.

Many of my cases have this experience; they may go for a week or for two weeks without any trouble, when, either with or without any exciting cause, a

volley is discharged, and for a day, or several days, they are nervous, irritable, neurasthenic, or certain special symptoms—such as sweating of the hands, agoraphobia, and aching of the loins—are made worse.

This phenomenon is never physiological, any more than an attack of diarrhoea is physiological; it is both a result and a cause of morbid states, either local or general. It may not be of a serious or terrible character. It may be a condition that time and nature will cure; but it is none the less, so far as it goes, a disease.

3d. When the emissions are induced by slight reflex irritation, or, subjectively, by mind acting on body.

A patient now under my care for sexual debility had an emission while sitting in a barber's chair; the result of the friction attending the operation of shampooing the head. This man is not often troubled by emissions, although he has other signs of genital disorder; but in this instance the emission was certainly pathological, and could not have occurred in a perfectly healthy individual. Curling mentions a similar instance of emission following reflex irritation. In a case of facial spasm that I was treating by large doses of conium, in combination with electricity, two emissions occurred while riding in a street car. The patient was reading a paper, not thinking of himself or of sexual matters. He is a person of more than average vigor, and is married, and not accustomed to involuntary emissions. It is probable that the conium long continued had produced its physiological effects, relaxing the muscular system, and that the excitation produced by the jolting of the car was sufficient to act as an exciting cause. The conium was stopped, and he has not since been troubled.

In this line come those quite common cases where the discharge comes before intromission, from the mere touch or contact, or from the friction of the clothing. Phenomena of this kind occurring rarely or often—once a week or once a month—are pathological; just as incontinence of urine is pathological, and, like that condition, may require treatment.

It is a morbid symptom when mental influence alone, without any external irritation, direct or reflex, brings on an emission. A physician, who consulted me in regard to himself, observed, as one of the earlier indications, that something was wrong with the nervous system, that simply hearing by accident amatory conversation in an adjoining room brought on an emission. The same gentleman also noticed as another morbid symptom, that very trifling mental excitation caused a slight discharge from the penis—weeping of the prostatic and Cowper's gland fluids; and that this was an indication of nervous disease subsequent history established; for a degree of genital debility, together with general nervousness, made it necessary for him to seek advice and treatment, as a result of which the parts quickly improved in tone.

This gentleman, I may say, was of mature years, clear-headed, and in no sense imaginative, and of a very large professional experience—less likely than many others to observe wrongly in these matters.

This weeping of the penis on mental excitation is not of course true spermatorrhoea, as the laity suppose, but it is pathological, a sign of genital weakness, and may or may not be the precursor of more serious symptoms. A patient of mine was so annoyed by these diurnal discharges appearing after and on very slight excitement, as during a bath even, that I told him to save some of the fluid, and have it examined by the microscope. It was found that it con-

tained no semen, but the fluid of the prostate and Cowper's glands.

4th. When they accompany or follow acute or chronic disease, and disappear with the disease.

Spinal cord affections in certain irritative stages and various febrile maladies have involuntary seminal discharges as one of their results, which results cease or are modified by the disappearance of the cause. The discharges in such cases are not always very frequent, but they are pathological, not physiological.

5th. When they take place in connection with any of the stages of impotence, and even when there is opportunity for frequent intercourse.

Those in whom the emission is too early after introduction, or who cannot have coitus frequently, are often annoyed—whether married or unmarried—by these involuntary discharges. With increase of tone, both the emissions and the lack of genital power disappear.

Quite a large number of cases of emissions appearing in this way in the married have been under my care. Indeed, I have never seen worse cases than some of those who are married.

6th. When the emissions occur at stool—diurnal pollution; or flow out with the urine—true spermatorrhœa.

If the urine of patients complaining of sexual debility be carefully and frequently examined by experts with a microscope, it will be found that true spermatorrhœa,—real flowing away of the spermatozoa with the urine,—is more frequent than any of us have suspected. A single examination, however carefully made, is not sufficient to disprove the existence of true spermatorrhœa; for, like the other morbid ingredients of the urine, the spermatozoa and spermatid globules are not necessarily found in every examination in any patient in whom the disease exists.

They might be found after an erection or excitement of any kind, when at other times they would not appear. Thus, in one of my cases two examinations brought no evidence of spermatorrhœa, but one made after an erection, though not after an emission, demonstrated, beyond any question, the existence of the disease. The history and symptoms of the case were in entire harmony with this diagnosis. The details of the case, which are very remarkable, will be published subsequently. No one, probably, will claim that the existence of spermatozoa in the urine is normal, and if they are found even in one examination out of six, it would indicate a pathological state. It is certain that examinations made in the way here described prove the existence of this condition in quite a considerable proportion of patients of sexual exhaustion. In cases where emissions are not especially frequent; in cases even where they are quite rare, spermatozoa and spermatid globules are sometimes found. But they are never found—according to my experience—in persons who are otherwise healthy; they are always accompanied with some vice or with a number of the symptoms of sexual exhaustion; for example, palmar hyperidrosis, anthropophobia, or fear of society, or agoraphobia, asthenopia, atonic voice, or impotence in some one of its stages, pain and weakness in the dorsal or lumbar spine, spinal irritation, frequent micturition, oxaluria, mental depression. A recent authority on these subjects states in substance these two propositions: first, that true spermatorrhœa is rarely seen even by specialists; secondly, involuntary emissions occurring two or three times a week are not pathological. Neither of these propositions is quite correct. They are suggestions or adumbrations

of the truth, rather than the truth itself. If the spermatozoa are not more frequently seen in the urine, it is partly because they are not more frequently looked for; and the frequency with which emissions occur is but one element, and that a minor one, in determining the question whether they are or are not pathological.

The facts here stated are so opposed to the almost unanimous teachings of all the writers upon these subjects, that it is proper to explain under what circumstances the examinations of the urine were made. In order to guard against the error which might come from the microscopist seeing what he expected to see, I sent the specimens of urine to Dr. Mittendorf, without giving him any information in regard to the patient. In the majority of cases he did not know what symptoms the patient had, or what sex, age, or condition the specimen represented.

Different forms of disease—kidney and bladder, and various phases of neurasthenia and other nervous diseases—were sent, at some times promiscuously; and it is an interesting illustration of the precision that this branch of science has attained, that with all the sources of error thus eliminated, no demonstrable mistake has ever been made.

But morbid emissions and true spermatorrhœa, though more frequent than is believed in the profession, are not always such terrible diseases as the laity believe; they are conditions that by proper management are relievable and curable.

These general principles are illustrated in the history of the following cases:

CASE VII.—A young gentleman, 27 years of age, consulted me for seminal emissions, with various symptoms of nervous exhaustion associated. The emissions were not very frequent, sometimes not as often as one a week; sometimes two or three followed each other on successive nights.

The appearance of the gentleman would indicate pretty fair health, and yet there was, as is often found in cases of neurasthenia, a degree of insomnia and mental depression. There was no real hypochondria, no disposition to magnify, or, to any great extent, to worry. There was the usual history of masturbation in his youth, but it had not been carried to very great excess. There was also the very common symptom of sweating of the palms of the hands. His circulation was not entirely good. Here was evidently a pathological state, though not of the severest order. Although the emissions were not frequent, yet they came in such a way that they had both temporarily and permanently injurious effects, for he was always worse in the mornings after there had been the involuntary emission. There was true spermatorrhœa. The nervous sensitiveness of the patient was illustrated by the fact that there was a tendency to faint on the application of the faradic current of electricity. The galvanic current, which is usually more powerful, had no such effect. He was treated with central galvanization, general and local faradization. The localized faradization was used externally and internally; he was treated on the principle prescribed in the first series of this paper. The result in a few weeks was an entire cure, which, as I afterwards learned from the patient, was permanent.

The above case illustrates two points: *First*, involuntary emissions, even when pathological, are not necessarily accompanied by hypochondria; *secondly*, they can be controlled by treatment even when the patient remains unmarried. In some cases involuntary emissions have been cured by treatment, although the accompanying symptoms of nervous debility were unaffected.

The patient has occasional emissions now, but they are not sufficiently the cause or effects of disease to require treatment.

The noteworthy fact in this case was, that the improvement took place while the patient remained unmarried. The indiscriminate prescription of marriage for all such cases, and all cases of sexual exhaustion, is oftentimes impracticable, usually unnecessary, and sometimes unscientific. All or nearly all cases can be helped without resorting to marriage, while in some instances marriage is to be for a time deferred. The large number of cases of involuntary emissions and impotence in the married is the best of all arguments against urging marriage as a specific for all forms of genital weakness. Marriage is sometimes a good hygienic remedy for hysteria in women, as it is sometimes for sexual debility in men; but it is no more a specific for the one than for the other.

CASE VIII.—A lad, 18 years of age, consulted me in the fall of 1878, for the following symptoms: Sweating hands (palmar hyperidrosis), dilated pupils, downcast eyes, anthropophobia or morbid fear of society, mental depression and a tendency to jerking of the limbs, not only at night, but even when sitting or standing. Even when sitting in the office while being treated, his feet would involuntarily move up and down. There was also the redundant prepuce, but not real phimosis. There was the almost invariable history of masturbation, begun at the age of thirteen or fourteen, and there was the usual results. The involuntary emissions came on only at night, were regular in appearance, and were not usually more than six or eight times a month. They were followed frequently by pains in the back and by aggravation of all the other symptoms of which I have spoken. In this case there was a certain degree of hypochondria, but it was not of a profound character. The patient was treated electrically in central and local methods, with hypodermic injections of atropia; internally by gelsemium, zinc, arsenic, and other sedatives. I lost sight of the patient before wholly restored, but he was under observation long enough to reduce the emissions in frequency, and especially to mitigate the evil effects that followed them.

In the above case the frequency of the emissions was certainly not great. According to the authorities, the patient was not in a pathological state, and yet, if the above symptoms did not indicate disease, certainly no symptoms can indicate chronic functional nervous disease. After allowing all that can possibly be claimed for the action of the mind on the body in producing disease, there remains clear proof of the actual influence of sexual disorder, producing a group of nervous symptoms independent, or at least partly of the mind—the fear, the expectations of the patient. The group of symptoms by which we are wont to diagnose such diseases, for example, as locomotor ataxy, spinal paralysis in children, hay-fever or small pox, and diphtheria, are not more truly diagnostic of those diseases than is the above group of symptoms diagnostic of sexual disorder. When a man has these symptoms together, either alone or in conjunction with others, which will be mentioned in the course of these articles, the diagnosis, neurasthenia of a sexual origin, can be made without hesitation, whether the involuntary emissions are frequent or infrequent. In the majority of these cases the involuntary emissions occurring rarely, or infrequently, follow the stopping of the habit of masturbation, and themselves act as causes of nervous symptoms. The whole system becomes involved; the treatment therefore should be general as well as local.

That involuntary emissions may occur in the married as well as in the unmarried, or those who have full opportunity for normal coitus, is illustrated by the two following cases:

CASE IX.—A number of years ago a young gentleman, about 30 years of age, who had been several years married, consulted me for very frequent-occurring emissions at night. He was of a very slight build, of the nervous diathesis, and, at times, had been excessively indulgent. There had also been self-abuse in early years. The involuntary emissions would appear, even when a few nights before there had been opportunity for emission in the natural way. He did not have all the symptoms connected with the emissions that sometimes is seen in unmarried young men. He was not at all hypochondriacal. I treated him for a considerable time by the sounds, by electricity connected with the urethral sounds, by central and general application of electricity, and a part of the time by sedative and tonic medicines. The case was more obstinate than oftentimes similar cases are in the unmarried. He did not respond rapidly to the treatment employed. But after a number of weeks the improvement was of so positive a character that it was deemed no longer necessary to continue the external applications; tonic medicines were advised for some time.

In the above case the emissions were certainly pathological. They were the results of a debility—a relaxed and congested condition of the orifice of the prostatic region of the urethra.

CASE X.—Last year I was consulted by a gentleman in the beginning of middle life; unmarried, but had abundant opportunities for sexual intercourse; with symptoms of impotence of the first stage and involuntary emissions, unless he frequently indulged. If a week or two passed without coitus, involuntary emissions would appear at night. He was a gentleman of unusual strength, and had been accustomed to great freedom in sexual intercourse. The symptom for which he required aid was merely the beginning of impotence. He could not indulge so frequently or so satisfactorily as formerly. The disease in his case was purely local. There were absolutely no general nervous symptoms. There was not a trace of neurasthenia. In that respect the case is an interesting contrast to those above detailed in these papers. With persons who are strong, tough, wiry, excess makes itself felt, locally and not generally or constitutionally. He did not have any of the group of symptoms which I have stated as diagnostic of neurasthenia depending on sexual excesses. There was no sweating of the hands, no physical debility, no anthropophobia, aversion to society, no morbid fear of any kind, and not the faintest degree of hypochondria. He studied his symptoms calmly, sensibly, philosophically, and he desired relief both for what he already experienced, and for what he feared as a result in case he neglected himself. Locally, it was found on examination that the penis was cold at times, and on passing the sound with care blood would always appear, evidently coming from the prostatic region of the urethra. The patient was treated by the use of the sounds, by electricity, by the zinc combination, ergot, belladonna, and cantharides in very small doses. Chloride of gold was also employed, and at one stage damiana; at the same time it was especially insisted that abstinence for a time should be observed. The patient faithfully carried out every direction, and was rewarded by improvement of the most satisfactory character. He was warned against indulging as formerly.

He is still taking treatment a portion of the time. The only relapse that he experienced was for a period

of relative excesses, when he thought that his recovery was absolutely permanent.

In this case the involuntary emissions were surely of a pathological character, as is proved by these facts: First, they did not exist prior to the first stage of impotence. A person in general health, general and local, will not have emissions several times weekly, when he has frequent opportunity for normal intercourse. Secondly, these emissions appeared with the symptoms of impotence. Thirdly, they have disappeared with the improvement of the local condition of the patient. In the same case the entire absence of emissions might be required as a pathological symptom, as indicating a degree of impotence not necessarily absolute, but a torpid condition of the parts. This condition is observed sometimes after many years' kept-up habit of masturbation, and sometimes after very prolonged continence. The following case illustrates this:—

CASE XI.—A gentleman about forty-one gave me this history. He began the habit of self abuse at the age of sixteen, kept it up a few years, then occasionally went with women. For twenty years he had been entirely continent. The emissions which he had had at one time disappeared. There was very much diminished desire, and scarcely ever any involuntary emissions. He desired to get married, and hence sought advice and treatment. There was a very much elongated prepuce, which, however, could be pushed back, and kept back, as it can in some of these cases, by a little effort. There was slight paresis of the bladder, with frequent micturition. The nervous symptoms were not very marked. There was an abnormal or mental irritability, a very frequent result of the sexual disturbances. Otherwise the person was in fair and enviable health, weighing about 155 pounds; a good sleeper; of good appetite, and without any mental depression or hypochondria. Examination of the urine revealed the presence of spermatozoa and spermatic globules; very little of the urates and the oxalate of lime, and a few epithelial cells, especially from the prostatic portion of the urethra. The gentleman had an appearance of youth—that is, he looked younger than he really was; a symptom oftentimes found in these cases, even in the worst cases of sexual causation. One proof that there was a vein of neurasthenia in the man, was that smoking a strong cigar would at once affect the man's nervous system, and the genital parts would suffer. There was at times an escape of semen at stools. Here is a case of true spermatorrhea, as is made absolutely clear by the examination of the urine, and by the diurnal emissions. In regard to these diurnal emissions, it may here be observed that non-expert testimony of the patients themselves may be generally accepted, for the prostatic and the urethral fluid does not come out in large quantities at such times; but even granting the liability of mistake in this respect, the examination of the urine at the hands of an expert settles the question of any doubtful case. This patient was treated in various ways. The details were changed from time to time: by the cooling catheter; by the urethral electrode, and by sounds; by central galvanization, general faradization, and electrolysis of the prostatic urethra, by strychnia, zinc, chloride of gold; and the improvement was sufficient to warrant his preparation for marriage.

In the above case the almost entire absence of seminal emissions, may be regarded as an evidence of declining power. It was an accompanying symptom of true spermatorrhea and impotence.

To what extent is asthenopia caused or aggravated by sexual disease?

That difficulties of the eye may be both causes and effects of nervous symptoms, is illustrated in the following very remarkable case, which is of about equal interest to the neurologist, the oculist, and the electrotherapist.

CASE XII.—A gentleman, 31 years of age, consulted me during the present year for headache and eyache, and other nervous symptoms that had interfered very seriously with his occupation, which was that of a bookkeeper. He stated that if he abstained absolutely from excitement and mental worry or effort, he felt almost entirely well; but if he indulged in these activities he would frequently have indescribable distress in the top and back part of the head. The ears would sometimes feel as though they would burst with pressure, and a feeling like that of a shock of electricity would go from the head to the extremities. Several years previous to consulting me he had had a very severe attack of nervous dyspepsia, and he subsequently became hypochondriacal. He also suffered from agoraphobia. He was in Brooklyn at that time, and could not cross the ferry alone, although able to walk many miles (I have seen and been consulted by a number of people who could not cross the ferry to New York; all of them recovered, and this man also recovered from this special symptom). Found it difficult to even leave the house where he was boarding. These mental symptoms had mostly disappeared when I first saw him. He had also been troubled at one time with fibrillary contractions, which have erroneously been supposed to be surely diagnostic of early stages of spinal disease. There had been beating and throbbing sensations in various parts of the body. He had also been troubled with sweating hands; so bad was he in this respect, that it was necessary for him to use a blotter to absorb the perspiration when he was writing. Some months before consulting me he had consulted an eminent neurologist in another city, who suggested that the eye was the cause of all the other troubles, and referred him to an oculist who diagnosed astigmatism, and found that the internal recti muscles were very weak. The trouble was chiefly in the left eye; and I may say, in the left side of the body and all through the left half of the brain. The left side of the face was most annoying. There was at times pain in the cheek, on the left side more than on the right. The patient had a habit of shaking one leg while standing. The application of atropia to the left eye at once relieved the pain. On being fitted with glasses, the pain returned, though in less degree. A very long vacation did a little, but no permanent good. When I first saw him he feared that he would not be able to take a position as bookkeeper that had recently been offered him. In this case the question to be answered was: What was the primary condition? Where did all these nervous symptoms start? I could get from the patient no history of sexual disorder of a very important character. Occasional emissions, to be sure, but not enough to suggest a pathological state. But on examination of the urine by Dr. Mittendorf, spermatozoa and spermatic globules were found, and the oxalate of lime. The result of this examination was a surprise both to the patient and myself, and it suggested a source of the irritation that might account for the obstinacy of the case.

I began to treat this patient at first generally, and then both generally and locally, with a marked improvement at once.

But the most satisfactory improvement was after

local galvanization to the weak muscles of the eye, and electrolysis of the prostatic portion of the urethra were employed. I have never seen a more sudden and gratifying effect of treatment in any case of long-standing nervous disease. He entered upon the duties of his new position, and is able to fulfil them with but little difficulty. Whereas formerly he could do very little, he now works over his books ten or fifteen hours a day. I should say that the previous treatment by bromides and iodids had no permanent effect, and he had also used various currents of electricity without satisfaction. I found that he was susceptible to certain medicines—muriatic acid for instance, with serpentaria, produced unpleasant effects.

In this case it is impossible to prove absolutely that the primal difficulty was with the sexual organs. It is possible that the neurasthenic tendency in his constitution, which he inherited from his father, first broke out in dyspepsia, and that the spermatic difficulty was secondary and the eye difficulty tertiary, but it is not impossible that the spermatorrhœa may have been the starting-point of all his troubles.

The asthenopia when it appeared became a cause or aggravation of all the other symptoms. I had the opportunity to show this case—which is so interesting both from a diagnostic and therapeutic point of view—to Dr. Lente and other medical friends. It was a whole clinique in itself, illustrating a large number of not very well-understood facts connected with neurasthenia.

TRAUMATIC ANEURISM IN THE EYELID, FOLLOWING AN OPERATION FOR TRICHIASIS.

By F. C. HOTZ, M.D.,

CHICAGO, ILL.

A SECONDARY hemorrhage occurring one week after an operation for trichiasis, is certainly a very uncommon accident. An observation, like the following, may perhaps not have been yet recorded, namely: that one of the smallest arterioles of the eyelid, which was wounded by the incision through the free edge of the lid, formed a small aneurism, which caused several troublesome hemorrhages. The fact that the patient, an unmarried woman, was afflicted with varicose veins of the lower extremities, probably is of some etiological interest, as it manifests a want of tonicity in the coats of her blood-vessels.

Miss R. H., aged 24 years, of Irving Park, has been troubled with granular conjunctivitis for the past ten years. There is now considerable atrophy of the conjunctiva of both lids of the right eye. The edge of the right upper lid is deformed, thick, and rounded. The eyelashes are growing irregularly, a great many being directed downward, so that they rub over the cornea at every movement of the lid or eyeball. This constant mechanical irritation resulted in pannus of the whole cornea. Patient is of a very nervous temperament, and has numerous varicose veins of the lower limbs. Within the past four years she had several bad bleedings from ruptured varices.

On March 14th I performed an operation for trichiasis. The free edge of the upper lid was split, and three sutures were put into the cutaneous wound. The reaction was very moderate. On the third day the sutures were removed; the external wound was found healed; the gap along the free edge of the lid was filling up with granulations; the eyelashes were everted; and the lid was neither swollen nor painful.

The conditions were so fair that I had not the slightest hesitation in allowing the patient to return home.

March 20th. Her mother called on me this morning in great haste and fright. She informed me that the eye had been doing quite well until day before yesterday. On that day it bled a little; yesterday the upper lid was swollen, but the swelling subsided, when in the afternoon the eye bled again. Towards evening the bleeding returned, and this time was so profuse that the blood ran down the cheek in a smart, red current. They put thick layers of cotton on the eye; in fact, covered the whole right side of the face with it; and finally, the bleeding stopped. It had not bled during the night nor this morning, when she left home. She stated that the blood seemed to come from underneath the lid. I found my patient in bed, greatly frightened; her face wrapped up in cotton, which underneath had become saturated with blood, and stuck tightly to the skin. By continuously soaking it with warm water, I succeeded in removing the cotton without in the least disturbing the lid. The lid was not swollen; the cutaneous wound was still united; the incision into the free edge (made for the purpose of splitting) was cicatrized, except at a small spot in its centre. There I noticed a globular, dark red, soft protrusion of about two millimetres in diameter. I took it for a small button of granulations, and thought that by winking, the friction of the lid against the eyeball occasionally chafed off the surface of these granulations, and so started the bleeding. Upon this supposition, I snipped off the supposed granulations with a pair of fine curved scissors. The removal was followed by a hemorrhage, which seemed to me altogether too brisk for bleeding granulations. It showed a decidedly rhythmical impulse, and was evidently arterial. I could easily control it by pressing the lid gently, but firmly, against the eyeball. When the small wound was cleansed, and all coagula were removed, it looked like a small cavity lined by a membrane, and in its depth I noticed a small opening, from which I could see the blood welling out as soon as I let up on the pressure. That which I had removed with the scissors was not solid granulation tissue, but a hollow membranous shell of about three-quarter section of a globe. I then at once recognized the real nature of the granulation-like protrusion; it was an aneurismal enlargement of the end of one of the arterioles, which had been cut in splitting the lid. When cut, its lumen was at once closed by the contraction of its wall, and sealed up by a coagulum. Therefore, no bleeding occurred during the first week after the operation. But during that time the thin wall of this arteriole was gradually expanding until a small aneurism was formed, which filled the gap of the wound in the centre of the tarsal border, and protruding a little above the surface of the latter was rubbing against the eyeball and the lower lid, when the lids were moved. This continuous friction caused an erosion of the aneurismal sac; the eroded part of its wall became so thin that it could no longer withstand the impulse of the blood pressure. It burst, and a hemorrhage ensued. At first probably the rent in the aneurismal sac was very small, and soon occluded by a fibrinous clot which arrested the hemorrhage. This would account for the fact that twice the bleeding was very insignificant. The third time, however, the rent probably was larger, and the bleeding became profuse and alarming.

While pressure upon the lid was arresting the bleeding, I grasped with a pair of finely-toothed forceps the remaining part of the aneurismal sac, excised it with curved scissors, and touched the little wound

with diluted tincture of perchloride of iron. Nothing further occurred. After five days the wound was found firmly cicatrized, the lid doing well.

April 15th.—Patient called at my office. Her eye has not troubled her since. The lid appears quite natural, opens easily; lashes all well everted, and cornea almost clear.

181 CLARK STREET, CHICAGO.

Progress of Medical Science.

FUNCTIONAL OBSTRUCTION OF THE INTESTINE, PROBABLY OF HYSTERICAL ORIGIN.—Dr. G. W. H. Kemper gives the following interesting history: The patient was a young woman, twenty-four years of age, who had been married one month. She at first suffered from slight nausea and indigestion, followed by a light and easily controlled attack of diarrhœa. Two or three days after the cessation of the diarrhœa some uneasiness was felt in the bowels, and a purgative was administered, but rejected from the stomach. Vomiting became more severe, and, on the fourth day, was stercoraceous. The temperature and pulse were nearly normal, and the patient merely complained of uneasiness in the abdomen. This region was thoroughly examined, and also the rectum and vagina; no knot or invagination could be discovered. Belladonna was given in moderate doses, and, when active restlessness occurred, morphia, combined with minute doses of calomel. Copious injections of warm water were thrown daily into the colon by means of elastic tubes. The body of the patient was occasionally inverted and manipulations made over the abdomen. Upon the fourteenth day of the disease three copious alvine evacuations occurred in rapid succession.

During the entire illness the constitutional disturbance was but slight, and the patient's strength and embonpoint were well preserved.

Three days after the bowels were moved the patient became morose and melancholy, followed by alternate fits of crying, laughter, and screaming. This hysterical condition continued for three days, and then suddenly disappeared. This hysterical condition, together with the fact that none of the symptoms indicated intussusception, serve to show that the intestinal obstruction was probably of an hysterical nature.—*The American Practitioner*, May, 1879.

NEW METHOD IN THE TREATMENT OF ACUTE CYSTITIS, OR OF ACUTE EXACERBATIONS OF CHRONIC CYSTITIS IN WOMEN.—This article constitutes an exceedingly interesting report on the result of Dr. Gehrung's new method in four cases, selected from a larger number in his practice. The plan of treatment is carried out as follows: The neck of the uterus is surrounded with a few small wads of cotton. This is followed by a large wad or two, thoroughly compressed between the fingers to facilitate introduction into the vagina, where, when let loose, it enlarges by its inherent elasticity, and fills the canal. After careful adjustment of these wads, the bladder is elevated and compressed against the pubes and abdominal wall, so to speak, between two elastic media. This cotton packing must be withdrawn and a fresh one reapplied as soon as pain and distress recur (two or three times within the first twenty-four hours, and then once or twice daily in very acute cases). Dr. Gehrung thinks that the success of this method depends upon the fact

that it enables the bladder to obtain rest. It also elevates the bladder, and enables it, even if the contractility of the organ is lost, to empty itself completely. The support and compression are also valuable factors. In cases of chronic cystitis, Dr. Gehrung prefers to use his anteversion pessary instead of the cotton packing. This pessary is entirely intravaginal, reaches from one side of the rectum to the other without molesting it, and presents two horizontal bars to the posterior wall of the bladder. The following is the history of the most striking case:

Mrs. L. V., æt. 40 years, had been under treatment four years for chronic cystitis. The production of an artificial vesico-vaginal fistula had been finally proposed as a last resort. When the patient first came under Dr. Gehrung's observation she was unable to walk or stand straight, and, even while sitting, could not, on account of pelvic pain, raise her arm to her head. Examination showed anteversion of the uterus, some enlargement of the organ, endometritis and tenderness of the pelvic organs, especially of the bladder. The night before treatment was begun, the patient micturated forty-nine times within two hours. The uterus was replaced next morning with one of Dr. Gehrung's anteversion pessaries, which not alone replaces the anteverted uterus, but also elevates and supports the bladder. After rising from the operating table, the patient stood perfectly erect, and could raise her arms as high as she wished. During the ensuing night she only emptied her bladder from ten to fifteen times. In two weeks the patient only micturated once or twice during the night, and continued steadily to improve. Within three weeks later she had entirely recovered, and has remained so since (four years).

PARAPLEGIA IN SYPHILITIC SUBJECTS.—Dr. E. C. Seguin reports the histories of six interesting cases of this disease, and presents the following considerations with regard to the treatment of severe cases:

1. To keep the bladder empty, and to prevent or reduce cystitis. This is done by removing the urine two or three times a day by means of perfectly smooth, soft catheters, which are to be kept in carbolized water when not used. If cystitis exist, injections of lukewarm water, of borated or carbolized water, will do good, or even cure the disease.

2. To prevent bed-sores, by keeping the sheets and shirt of the patient perfectly smooth and taut; by preventing urine from running under him; by frequent sponging with alcohol and water; and by the use of powders. If bed-sores have formed, they should be treated with ice or snow poultices for ten minutes, twice a day, and stimulating dressings for the rest of the time; gangrenous shreds should be picked out, and the recesses of the sore injected with strongly carbolized water. Pressure should be removed by change of posture and by appropriate pads.—*Archives of Dermatology*, April, 1879.

THE NEW HAMPSHIRE STATE MEDICAL SOCIETY will hold its Eighty-ninth Annual Meeting in the city of Concord, June 17th and 18th.

THE DIAGNOSIS OF INSANITY.—The third spring course of clinical lectures on the diagnosis of insanity will be delivered at New York City Asylum, Ward's Island, by Dr. A. E. Macdonald, medical superintendent, commencing June 7th, and continued June 14th, 21st, and 28th.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

W.M. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, June 14, 1879.

MR. LISTER'S ANTISEPTIC TREATMENT.

THE antiseptic method in surgery, introduced by Mr. Lister, in which carbolic acid is applied in spray form, has found so wide an acceptance, that it has almost been considered one of those fortunate suggestions which would finally graft itself upon our modern practice of surgery.

But surgery is a progressive art, and we are therefore not surprised to find that while this method is still upon its trial, Dr. Perrin, in the *Union Médicale*, expresses the opinion that they have long had in France an antiseptic treatment which is probably better, and he considers more simple and practical, than that of Mr. Lister.

It consists in the use of alcohol in the place of carbolic acid.

M. Perrin, in giving his reasons for his preference of this agent, suggests that Lister is in error in one of the fundamental principles on which he bases his well-known treatment. Thus he asserts, that in all putrid alterations there are two things to be considered, the germ and the soil which suits it, and he contends further that Lister has only had the germ in view, and therefore his method is defective. M. Perrin claims that he has made a number of experiments, which seem to prove that carbolic acid spray has really no influence on the evolution of atmospheric germs in liquids suitable for their culture, and on the consequent phenomena of putrefaction. On the other hand, alcohol diluted with an equal volume of water, he says, acts on the soil, that is, the wound; renders albuminous liquids imputrescible; has considerable coagulating power; readily stops bleeding from vessels of small calibre; quickly moistens cotton; and penetrates into the tissues of the body, without having the instant action of carbolic acid.

In military surgery, especially, M. Perrin looks on alcohol as the agent *par excellence*, and he sometimes

applies it to wounds in wadding saturated with it (a drainage tube being added); and sometimes (in cases of contused wounds, complicated fractures, etc.) he practises alcoholic injections and irrigations.

In placing before the profession the views of M. Perrin, we refrain from giving any decisive opinion on the issue thus raised. This is a question which can only be answered by practical experiments, and it would be clearly a waste of time to theorize on a matter the truth or error of which is capable of such easy demonstration.

But without prejudicing the question, we may express some doubt that Mr. Lister took but a partial view of this subject. The masterly manner, however, in which he worked out his antiseptic treatment does not preclude the possibility that he overlooked such a fundamental point as M. Perrin suggests. Without doubt Mr. Lister aimed at the destruction of the germs, not only in the air and upon the instruments and the appliances, but within the wound itself, and he clearly believes that the carbolic acid spray effects this object.

M. Perrin now positively asserts that he has demonstrated, by experiments, that the carbolic-acid spray has no influence on the evolution of atmospheric germs in liquids suitable for their culture. The issue being clearly stated, let this point be first satisfactorily settled, and as it is capable of practical demonstration by simple tests we trust it will be done at once.

It is a secondary consideration to decide whether alcohol renders a wound incapable of sustaining living putrefactive elements. For, if Mr. Lister is correct in stating that carbolic-acid spray is sufficient, the question drifts into the minor consideration whether alcohol is equally potent in this respect, and, finally, which of the two agents is the most suitable for the purpose. Additional importance is given to the proposition to substitute alcohol for carbolic acid in the antiseptic treatment, from the belief of many that some of the fatal cases which have followed Lister's treatment were due to the absorption of carbolic acid applied to the wounds. Such an instance was recently brought before the Clinical Society of London by Dr. A. Pearee Gould, who pointed out, that in this particular case all went well with the patient for forty-eight hours, and then suddenly, and coincidentally with the excretion of carbolic acid in the urine, the fatal symptoms set in, which he observed to be not local, but general in their character. Apparently Dr. Gould had not heard of M. Perrin's alcoholic antiseptic treatment, but he prophetically observes, in a letter recently published, that "the future of the antiseptic treatment is not bound up with carbolic acid."

This is a matter of great importance to the medical profession, and highly interesting in its scientific bearings. We know many whose decision on this question would be received with respect, and we confidently look to them for a prompt solution.

IS VACCINATION DANGEROUS?

OUR attention has been called to a leading article in a Delaware newspaper, headed "Is Vaccination Dangerous?" in which it is stated that a lively controversy is now going on in Europe as to whether vaccination is an efficient and advisable method of preventing small-pox. We would hint to our Delaware brother that this is pretty old news, for it is full twelve years since "the renowned Dr. Collins of London," had his say on this subject before a Parliamentary commission, whose proceedings, published *verbatim* in a huge blue-book, form very wholesome reading for any one who may have been duped into according the slightest weight to "the renowned Dr. Collins" and his fellow agitators of the "Anti-Vaccination League," whose statements and fanciful deductions met the fate which overtakes the dew when the sun brings his beams to bear upon it. Silly and harmful as these vaporings are, however, by dint of incessant repetition they take hold upon the minds of simple people, especially in times when, as at present, small-pox has for a time ceased to threaten; but the logic of facts, as brought out by an epidemic, never fails to consign them again to obscurity. Men, and particularly Anglo-Saxons, object to having anything—even blessings—thrust upon them, and we cannot avoid the conclusion that this anti-vaccination twaddle is kept alive by the compulsory vaccination laws in force in some European countries. In this country the opposition to vaccination is too insignificant to call for notice. Should this state of things ever become changed, the newspapers will do well to publish freely whatever any one may have to say on the question, for the truth never permanently suffers from rough handling. As things are now, we should not have felt called upon to notice the article in question, except for the fact that it couples the name of Dr. Edward Ballard with those of "the renowned Dr. Collins," and others of that ilk. When we remember that Dr. Ballard is the author of the best essay on vaccination ever published, in which, while treating the anti-vaccinators with the utmost fairness and courtesy, he grinds their arguments to powder, we must conclude that the grievance under which the League chafes must have rather palled upon the public, else they would scarcely put forward, to sustain their cause, a man whom, next to Mr. John Simon, they have most cause to fear—the man whose essay bore off, much to their chagrin, a prize offered by one of their own set. It is so rarely, we regret to say, that a medical writer views with fairness the positions of his opponents, that one who does so may surely claim our aid in defending his utterances against such gross misrepresentation as the newspaper article here referred to gives to Dr. Ballard's account of the Rivalta cases of vaccinal syphilis. The fact that Dr. Ballard has carefully and fairly examined the vaccinal syphilis and animal vaccination questions, far from

putting him in the attitude of an opponent of vaccination, makes him *ipso facto* one of the most unanswerable of its adherents.

Reviews and Notices of Books.

THE NATIONAL DISPENSATORY. By ALFRED STILLÉ, M.D., LL.D., and JOHN M. MAISCH, Ph.D. Philadelphia: H. C. Lea. 1879. Pp. 1,628.

First Notice.

THIS new candidate for professional and pharmaceutical favor is a handsome volume, rivalling in size the old familiar U. S. Dispensatory, and as its intent is to satisfy the usual "long-felt want," we have examined its pages with more than usual interest and care. That a dispensatory in keeping with the times was greatly needed was clearly recognized during the discussions two or three years ago concerning the U. S. Pharmacopœia, and the proprietors of the former work promptly brought out a "revised" edition, in which the evidences of revision were not as distinct and unmistakable as many would have wished. This created the opportunity for the possible success of a rival publication, whose objects should be the same, but whose merits should be greater. Were the national the only dispensatory in existence we should not hesitate to commend it highly as the best work on the subject attainable; but as there is another and an older work that for forty years or more has enjoyed this distinction, we shall in a measure be compelled to institute a comparison between the two; but before doing so must consider the plan and the contents of the work that more immediately concerns us. The scope of the dispensatory is two-fold: pharmaceutical and therapeutical. In the first place, the work contains the text of the pharmacopœia, with comments on the various processes for the preparation and compounding of officinal and non-officinal drugs; in the second place, it supplies a large amount of pharmacological and botanical information, thus supplementing the deficiencies of the pharmacopœia in these respects. The fact that such a supplement is necessary is somewhat scandalous, and reflects no credit on the revisers of the pharmacopœia, for it must be remembered that that work is supposed to be representative in its character, while the dispensatories are purely private business enterprises, and as long as the pharmacopœia can be kept in a condition that makes it almost worthless as a work of reference, so long will there be a market for the dispensatories. It has, indeed, been hinted that this state of affairs is not altogether the result of chance, and we cannot conceal our fear that the appearance of a second dispensatory will tend still further to delay our hopes of pharmacopœial improvement and reform.

The therapeutical scope of the dispensatory should be the collection of the experience of the profession with the various articles of the materia medica, devoting comparatively little space to those that are well known and described in every text-book on therapeutics, and giving the fullest possible account of active drugs that are but little known, or that have been employed by a few practitioners only. The physician does not turn to the dispensatory in search of therapeutic information concerning mercury, opium, or belladonna, but rather to some standard text-book on materia medica; on the other hand, if he wishes to know something about a little known drug, that

has been used for something or other by somebody, he naturally turns to the dispensatory in the hope that he will there find what it has been used for, who has used it, and where they tell about it. From these standpoints we will consider the work before us.

As regards the pharmaceutical portion of the work, we can say but little, as lack of knowledge, too frequent among physicians, of pharmacy, pharmacology, and botany, unquestionably forbids any critical consideration, on our part, of these portions of the work. We may remark, however, that the arrangement is convenient, the style pleasing, and the frequent reference to modern as well as the older researches indicates that the author is familiar with the subjects he has chosen to handle, and as these concern matters of fact rather than of opinion, the statements of the author may, we presume, be accepted without question.

The portion of the work prepared by Prof. Stillé is the one that particularly interests the physician, and it is to this that we will devote special consideration. It embraces about one-fourth of the entire work, and is devoted to the physiological action and medical uses of the various drugs. In the majority of instances no reference to the physiological action is made, either because this action is unknown, or perhaps because Prof. Stillé regards a knowledge of it of little importance as an aid to the intelligent use of drugs. We believe ourselves justified in this inference by the previous writings of the author. In the preface to the last edition of his *Therapeutics and Materia Medica* he says: "In the first edition of the work he contended against the mischievous error of seeking to deduce the therapeutical uses of medicines from their physiological action. Continued study, observation, and reflection have tended to strengthen his conviction upon this subject," etc. We give this quotation, as it is the key-note of the work before us, and we will see as we advance how far it is justified by the facts recorded by the author. In dealing with the therapeutical aspects of drugs, the author rarely gives the statements and views of others, and almost never the facts and evidence which have led them to their conclusions, but instead, his own inferences and inductions, in the formation of which he is naturally influenced to a greater or less degree by what the mathematician would term the "personal equation." This method of treating the subject will specially commend the work to those who, too indolent or too busy to examine the facts for themselves, are perfectly willing to have this done for them by another. There are some, however, who prefer thinking a little for themselves, to whom the present work will prove exceedingly unsatisfactory, as it is filled with the most dogmatic statements unsupported by evidence or argument. One of the most useful features of the U. S. Dispensatory are the frequent references to original sources of information, thus enabling the reader to obtain full details concerning the matters referred to. In the National Dispensatory these are uniformly omitted, a defect that makes the book nearly valueless as a work of reference. The expressions "is said" or "is stated" occur in almost every section contributed by Prof. Stillé, but by whom said, and where said, the reader is uninformed.

With reference to drugs with which the author is practically familiar, his own dicta concerning their sphere of usefulness must be accepted as the conclusions of one eminently fitted to observe facts and to draw reasonable inductions from them. But when it comes to drugs that he has never employed, the case is different, and we are hardly prepared to definitely

accept the condemnatory statements that he makes concerning many of them. His method of arriving at a conclusion seems to have, to a certain extent, a mathematical basis, *i. e.*, if ten observers have obtained certain beneficial results in the use of a given drug, and twenty others have failed to obtain them, the negative testimony outweighs the positive, and the drug is labelled as useless, a method that reminds us of the prisoner who was acquitted because ten witnesses testified that they did not see the crime committed, while but five swore that they did see it.

In view of the foregoing we will introduce a few quotations with comments, and also call attention to some other points of interest, commencing at the beginning of the book and going through it in order.

ARSENIC, p. 24.—"A longer continuance of the medicine is apt to occasion eruptions of the skin, particularly urticaria, pityriasis, and psoriasis." This is a remarkable statement in view of the fact that arsenic is almost universally employed for their relief.

SALICYLIC ACID, p. 75.—"In this case is presented an apt illustration of the error of deducing the therapeutical uses of a medicine from its apparent physiological action." We think that the quotation concerning arsenic above given is still more "apt."

ACONITE, p. 95, appears not to have yielded good results at the hands of the author in those affections in which it has been commonly employed. This surprises us, as we know of many physicians to whom a vial of aconite is as indispensable a companion as a hypodermic syringe.

The long line of advocates of aconite, from Störck to Gubler, should teach us that there is an art in therapeutics, and that this art consists as much in properly handling powerful drugs as in the more delicate manipulations of ophthalmic surgery. Every one can give aconite, but it is not every one that gives it just at the right time, or in just the right quantity; and unless this is done how can good results be expected?

ALKEKENGI, p. 131.—To this plant a few words are devoted. Its diuretic powers have been praised by so many European writers that we are surprised that it is not in more general use. The only form in which it has been employed in this country, so far as we are aware, is in the shape of a proprietary medicine—Laville's gout pills—of which it is the principal ingredient.

ALOES, p. 137, is recommended both in *amenorrhœa* and in *menorrhagia*!

AMYL NITRITE.—Of this the author makes the usual statements, but neglects to mention the important discovery of Ringer—that the drug when given in appropriate doses is capable of relieving flushings of the face, so common and distressing to women—a fact that we have several times had an opportunity of confirming.

GOLD, p. 261.—"It is unnecessary to enter into any detail respecting a medicine which has deservedly fallen into disuse." This is certainly an extraordinary statement. Has Dr. Stillé forgotten the writings of Chrestien and Niel. of Logrand and Duhamel and Trousseau, of France, and the elders Cheesman and Delafield, of this city? It has taken the profession nearly three hundred years to learn how to employ mercury to the best advantage in syphilis (*vide infra*), and it may require the same length of time before some learn the proper and useful applications of gold in the same disease. It is not necessary to poison the patient, or "to produce a destructive activity in the morbid process," in order to obtain the best results. The dose mentioned by the author is $\frac{1}{10}$ grain of the

oxide. This is altogether too high. Better curative effects will follow smaller doses.

BURSA PASTORIS, p. 304.—“Its use is entirely obsolete.” This is curious, as we have seen some four or five recommendations of it in the journals of the last six months.

THE SULPHATE AND SULPHITE OF CALCIUM are mentioned, but not a word is said about the *sulphide*, now used by so many, following Ringer, for the control of suppuration. This drug is the *hepar sulphuris calcareum* of the older pharmaceutical writers, and was first brought prominently into notice, we believe, by Paping (1796) as a remedy against mercurial salivation.

CLEMATIS, p. 427.—Of this the author speaks by hearsay only. The drug is interesting, however, as having cured, at the hands of Störck (1769), the first case of gonorrhœal rheumatism of which we have found record.

CONIUM, p. 151.—Stillé recognizes the worthlessness of most of the *preparations* of this drug, but fails to call attention to the fluid extract prepared by Squibb, which we believe has given general satisfaction for uniformity and certainty of action.

CYCLAMEN, p. 487.—The interesting statement is made, on the authority of Vulpian, that if frogs are poisoned with this drug “their blood is found to contain a multitude of vibrios, some of which are even in the interior of the red corpuscles.”

DULCAMARA, p. 511.—Of this drug Stillé speaks more flatteringly and justly, we think, than most writers. He says that the best preparation is a decoction made from the fresh stems.

SCLEROTINIC ACID, pp. 535-538.—On the former page the dose of this new derivative from ergot is given as $\frac{1}{2}$ – $\frac{3}{4}$ grain, but three pages later it is stated to be $\frac{1}{2}$ to $\frac{1}{10}$ grain.

GELSEMIUM, pp. 593-664, appears to meet with but little favor from the author.

BROMIDE OF IRON, p. 612.—“There is not the slightest evidence of its ever having been useful as a medicine; and, as it is dangerously poisonous, it ought never to be used internally.” To this assertion we must certainly demur. Arsenic, strychnine, and atropine are also “dangerously poisonous,” but in appropriate doses are generally regarded as useful. We suppose no one would think of using this preparation when a sedative effect (like that of bromide of potassium) is desired, nor as an hematic in the place of the usual preparations of iron. We have, however, frequently employed it in doses of $\frac{1}{2}$ grain and upward, and we think with benefit; and Hecquet (*Recherches*, etc., Paris, 1877) recommends it in doses of $\frac{3}{4}$ grain or more.

BINOIDE OF MERCURY, p. 715.—“As an internal remedy it is superfluous, and dangerous unless very cautiously used”!!

PROTOIODE OF MERCURY, p. 717.—In syphilis “it should be given in doses of from three-quarters of a grain to one grain three times a day, and gradually increased until these doses are trebled, or more, provided that neither salivation nor diarrhoea occurs.” We must earnestly protest against such practice as this. Few patients would stand such dosing more than a week without the occurrence of salivation, serious depression of the spirits, and perhaps of the vital powers. Few, if any, modern syphilographers employ this drug in doses exceeding one-third of a grain. Under these and smaller doses the syphilitic manifestations disappear, and the patients grow fat and hearty, even with a continuance of the remedy for months at a time. Syphilis cannot be strangled

by a pound of mercury given at a dose, but it can be persuaded out of the system by the gentle allurements of minute but repeated doses. Too many competent observers have employed and still employ this plan of treatment to admit of any doubt of its efficacy. A hogshead of water may leave the stone unscathed, but if applied *guttatim* the result may be different.

We have not space at the present time for further comment. The quotations that we have given show that the work does not fairly represent the therapeutics of the present, at least as we have observed them in this part of the country. The therapeutic wave that is reaching us from the East (England) promises a milder system, but whether more or less successful time alone will tell. Although criticising the author's contributions to the National Dispensatory, we cannot forget that the last hundred years has given us, in the English language, but three standard treatises on *matéria medica*—those of Cullen, Pereira, and Stillé—works that will be held in honor for yet a hundred years to come.

Reports of Societies.

MEDICAL SOCIETY OF THE STATE OF NEW JERSEY.

ONE HUNDRED AND THIRTEENTH ANNUAL MEETING.

Held in Englewood, May 27 and 28, 1879.

(Special Report for THE MEDICAL RECORD.)

TUESDAY, MAY 27TH—FIRST DAY.

THE Society met in the parlor of the Palisade House, Englewood Cliffs, at 8 o'clock P.M., and was called to order by the President, DR. JOHN S. COOK, of Hackettstown. Among those who occupied the platform were the three Vice-Presidents, DRs. RODGER, DOUGHERTY, and OAKLEY, and the Secretaries and the Treasurer.

Prayer was offered by REV. DR. PAYNE, of Englewood.

The Committee on Organization reported the list of Delegates and Fellows. An unusually large number of both were present, every District Society in the State being represented.

ANNUAL ADDRESS OF THE PRESIDENT.

The President read the annual address, the subject of which was

“THE PROBLEM OF LIFE.”

Having portrayed the majesty of the human mind, its seeking after the true solution of great problems, the doctor discussed the many attempts to answer the question of “How life came on the earth?” He reviewed the theories of the ancients, and showed the effect of Pasteur's observations on germ-life in the development of Listerism. A large part of the paper was devoted to the Darwinian theory, its relation to the problem of life, and the conflict of science and religion. It ended with a philosophical discussion of the question, “What is the good of life?” the effect of the teachings of Schopenhauer and Nihilism, and the lessons to be drawn from statistics regarding the wastage and the limit of life.

DELEGATES FROM OTHER SOCIETIES.

Drs. Ferris Jacobs and S. O. Vander Poel, Honorary members, and Drs. James H. Eldridge and W. E.

Anthony, Corresponding Delegates, from the Medical Society of Rhode Island; Dr. David B. Van Slyck, from the Massachusetts Medical Society, and Drs. N. C. Husted, Robert Newman, and Professor Joseph C. Hutchison, from the Medical Society of the State of New York, were present, and were cordially welcomed by the President.

The Society then adjourned, to meet at 9.30 A.M. on Wednesday.

WEDNESDAY, MAY 28TH—SECOND DAY.

The Society was called to order at 9.30 o'clock by the President.

REPORT OF THE STANDING COMMITTEE.

The first business of the Session was the reading of the Annual Report of the Standing Committee. The Report of the Standing Committee is always a prominent feature in the transactions of the Society, and is always received with much interest.

DR. WICKES, who has been the Chairman of the Committee for many years, read the report, of which the following is a resumé:

EPIDEMICS.

Epidemics had not been prevalent. Scarlatina, diphtheria, and diseases of the alimentary canal had occurred in less than their usual amount. Diseases of the respiratory organs had been very general, and, in some large sections of the State, in the form of influenza, epidemic. Fevers, in their varied forms, and malarial poisoning, had been almost universal. Large portions of the State, where these agencies had been heretofore almost unknown, had been invaded. Its occurrence in regions where none of the usual causes recognized by sanitarians existed, pointed to the fact that the pestilence still walked in darkness and was governed by laws which our advanced methods of scientific research had not revealed.

NEW REMEDIES.

Among new remedies, salicylic acid and its salts were noted as reliable and most efficient agents in acute rheumatism. Reports regarding the use of the cinchona alkaloids tended to prove that, in double doses, cinchonidin and cinchona equalled quinine as antiperiodics. Carbolate of ammonia (gr. i. t.i.d.) had been used in Morris County successfully, instead of quinine, in intermittents. Dr. Kipp, of Essex, in a paper on glaucoma, commended the sulphate of eserine in the subacute form; and where that agent caused pain in the head, he had used, with good effect, the muriate of pilocarpia. Jaborandi had been successfully used in hydrothorax, Bright's disease, orchitis of mumps, and in belladonna intoxication.

One reporter complained of the fraudulent character of many of the elixirs, fluid extracts, and syrups put on the market by manufacturers.

It was a question for serious consideration whether the proprietary preparations, which now so abounded, wearing the livery of official compounds, and advertised and recommended in most of our medical journals, were not supplanting, in too great a manner and at the expense of efficient medication, the recognized remedies of our materia medica.

The committee proposed two questions to the members of the district societies for answer:

1. *The therapeutic value of ergot.*
2. *The value of pessaries in uterine displacement.*

In summing up the answers to the first question, they concluded that ergot was a valuable agent as a

uterine stimulant in parturition, but dangerous when used too early; a hemostatic in all cases of external or internal hemorrhage; invaluable for controlling the supply of blood to congested parts or organs; useful in congestive or nervous headache; a stimulant of muscular fibre; a good agent in cardiac palpitation, even better than digitalis or veratrum. In pneumonia, its action in changing the colored sputa was as prompt as quinine in intermittent.

The answers to the second question varied as widely as possible; many condemned, while many praised; language equally extravagant was used on either side; and though much instruction might be derived from the replies, no ultimate conclusions could be reached.

REPORT ON NECROLOGY.

The necrology of the year was as follows:

Edward D. G. Smith, M.D.; J. B. Jackson, M.D.; R. N. Bateman, M.D.; Frank Parsons, M.D.; J. N. Julian, M.D.; A. J. Krapon, M.D.; C. D. Deshler, M.D.; R. J. Whitely, M.D.; J. L. Taylor, M.D.; T. J. Conover, M.D.; Lemuel Burr, M.D.; Kent, M.D.; James Holmes, M.D.; H. H. Rheinhart, M.D.; ——— Gulick, M.D.

The report being before the Society for discussion, DR. HOPPER, of Bergen, referred to what was said in reference to the use of salicylates in rheumatism. He had observed in his practice markedly good results. In his own person he had recently been entirely relieved of a severe attack of acute articular rheumatism in a few days by them.

DR. RIDGE, of Camden, had also used the salicylates extensively, but with varied success. Ergot he had used extensively in nearly all forms of hemorrhage, and was much pleased with its action in these cases. He spoke disparagingly of the use of the elixirs and the proprietary medicines which have in a few years come into such general use. He was opposed to leaving the compounding of medicines to the exclusive control of the pharmacist.

DR. HERRAGE, of Worcester, advocated the use of salicylic acid and quinine. He was in the habit of prescribing iv. grs. of the acid every two hours to young children with diphtheria, and with markedly good results. He also was not an advocate for the use of the so-called proprietary medicines. He spoke commendatorily of the use of stem pessaries.

DR. OSBORNE, of Essex, had observed good results from the use of the salicylates in the treatment of rheumatism. He spoke of good results he had observed from the use of jaborandi in the treatment of tubal nephritis.

DR. CORSON, of Essex, was an advocate for the use of ergot in pulmonary hemorrhage.

DR. BODINE, of Mercer, had observed negative results only in the treatment of rheumatism with the salicylates.

DR. HUNT, of Middlesex, urged the importance of more accuracy in the observing and relating of cases.

DR. BALDWIN, of Middlesex, expressed the idea that the varied results observed by the members in the use of the salicylates and other drugs might be accounted for by the character of the drugs used.

DR. PEWEE, of Monmouth, was surprised to learn that any physician at the present day could doubt the contagious character of scarlet fever and diphtheria. He believed there was no better settled fact in medicine than the contagion of those diseases.

DR. ROGERS, of Passaic, preferred the salicylate of soda to the salicylic acid. The latter he had found to produce a great irritation of the stomach.

DR. JOHNSON, of Warren, had been pleased with

what he had observed in the use of salicylic acid in the treatment of diabetes mellitus.

DR. LARSON, of Monmouth, spoke of a form of influenza which had been of unusual prevalence in his county during the past winter.

ON THE USE OF ALCOHOL IN MEDICINE.

The report on the Use of Alcohol in Medicine, by DR. THOS. RYERSON, of Newton, was received and referred to the Committee on Publication.

DR. J. W. COBSON, of Orange, read an abstract of a paper he had prepared

ON A HEALTHY IMPULSE OF THE HEART AS A VALUABLE SIGN OF COMPARATIVE SAFETY IN THE USE OF ANÆSTHETICS.

The abstract was well received, and a copy of the paper in full was requested for publication in the Transactions.

REPORTS OF DELEGATES.

DR. LILLY, delegate to the American Medical Association, read his report.

DR. TAYLOR, delegate to the Pennsylvania Medical Society, also read his report. Both were referred to the Committee on Publication.

PUERPERAL CONVULSIONS.

DR. L. W. OAKLEY, third Vice-President, read a very exhaustive paper on Puerperal Convulsions, which was well received and a copy requested for publication.

DR. H. G. TAYLOR presented a paper on

UNITY OF THE MEDICAL PROFESSION.

which, at his own request, owing to the lateness of the hour and the press of business, was referred to the Committee on Publication without being read.

DR. A. CLENDENIX read a valuable paper entitled, A RÉSUMÉ UNIVERSAL, AND CONCLUSIONS THEREFROM ON YELLOW FEVER.

The paper will be published in the Transactions.

HONORARY MEMBERS.

Drs. David B. Van Slyck, of Massachusetts, Prof. Joseph C. Hutcheson, of Brooklyn, N. Y., and Prof. Brackett, of Princeton, N. J., were proposed for Honorary Membership.

DR. P. V. P. HEWLETT was appointed essayist for the next meeting of the Society.

It was voted that the next annual meeting be held in Princeton.

The assessment for next year is to be one dollar per capita for members of district medical societies.

OFFICERS ELECT.

The following were elected the officers for the ensuing year:

For President.—Dr. A. W. Rogers.

For Vice-Presidents.—Drs. A. N. Dougherty, L. W. Oakley, and John W. Snowden.

For Corresponding Secretary.—Dr. Wm. Elmer, Jr.

For Recording Secretary.—Dr. Wm. Pierson, Jr.

For Treasurer.—Dr. W. W. L. Phillips.

For Standing Committee.—Drs. S. Wickes, S. Lilly, and J. L. Bodine.

For Delegates to American Medical Association for 1880.—Drs. A. Clendenix, J. C. Thornton, C. O. Voorhees, William Pierson, Jr., L. W. Oakley, W. R. Fisher, S. Lilly, Wm. Green, John Wright, P. C. Barker Hildard, A. W. Rogers, H. G. Wagoner, Carlos Allen, C. F. Stillman, J. C. Johnson, and C. J. Kip.

For Delegates to Rhode Island State Medical Society.

—Drs. S. Pennington, and I. I. B. Ribble.

For Delegates to Connecticut State Medical Society.

Drs. W. A. Hopper and G. H. Ballenay.

For Delegates to Massachusetts State Medical Society.

—Drs. F. Wilmarth, Jos. Parrish, and W. L. Newell.

For Delegates to Vermont State Medical Society.—

Drs. P. C. Barker and W. W. Elmer.

For Delegates to New York State Medical Society.—

Drs. D. A. Currie, J. W. Hunt, and E. J. Marsh.

For Delegates to Pennsylvania State Medical Society.

—Drs. F. Gaunt, W. A. Newell, and S. Lilly.

The Society then adjourned.

CONNECTICUT MEDICAL SOCIETY.

Eighty-eighth Annual Meeting, May 28 and 29, 1879.

DR. C. M. CARLETON, PRESIDENT, IN THE CHAIR.

(Special Report for THE MEDICAL RECORD.)

THE Eighty-eighth Annual Convention of the President and Fellows of the Connecticut Medical Society was held in the city of Hartford May 28th and 29th.

DR. C. M. CARLETON, the President of the Society, welcomed the delegates in a brief address. The first day was devoted chiefly to business. The governing board of the Society consists of the President and the officers, five fellows from each county—save Tolland, which sends three—and the presidents of the eight county societies.

The President made a brief *resumé* of the business handed down from the last annual meeting.

SPECIAL AMENDMENTS.

Of this, mention was made of certain amendments to the by-laws, amendments to the charter of the Medical Department of Yale, a case of discipline, and the proposed act relating to medical tramps or itinerant practitioners.

One of the special subjects demanding attention at the present meeting was

THE PROPER MANAGEMENT AND CARE OF THE INSANE.

That the Society might receive proper information relating to the question, he had invited the Neurological Society of the City of New York to send a representative from its body, and, in accordance with the request, the Society had sent Dr. Wm. A. Hammond, of the city of New York.

STATE BOARD OF HEALTH.

The President urged the renewed co-operation of the profession with the State Board of Health. The support it had already received and its purposes and aims were heartily endorsed.

MEDICAL EXAMINER SYSTEM.

The medical examiner system of the State of Massachusetts was brought to the attention of the Society, and it was recommended that a committee be appointed to investigate the system with regard to its practical workings in that State, and to report at the next annual meeting the adaptability of the system to the State of Connecticut. The committee appointed consisted of Drs. C. W. Chamberlain, E. C. Kinney, and N. C. Wordin.

METRIC SYSTEM.

It was also recommended that a similar committee be appointed to report on the metric system.

COMMISSION OF THE BOARD OF MEDICINE.

Reference was made to the various resolutions of the Board and resolutions and amendments adopted at the last session during the session of the late Legislature.

REPORT OF THE BOARD.

In addition to the resolutions reported at the suggestion of the President, one was appointed to report next year with reference to the propriety of extending the office of coroner.

The President also announced the various regular sessions of the Society.

THE UNIVERSITY OF THE STATE OF NEW YORK.

The general committee was reported as the result of a committee on the fact that it was to have and report back the report of the Faculty who had been assigned the task of the study by consulting with the various departments, by conferring with the various departments and by general investigation and study.

A committee was also given to know the relations between the various county societies in respect to the fact whether a member of the New York State Society.

The Committee was also reported to have, when the committee reported the year.

On the subject of the fact whether a member, made an effort through its members, Dr. C. W. Chamberlain of Hartford. The committee was appointed with power to report to the Legislature for such amendments as might be properly agreed upon in a similar manner to the various departments of Yale, the medical faculty, and the Connecticut Medical Society, and reported as follows:

The report is given subject to medicine being the department from the Medical Society and the profession in the Medical School. This was retained unchanged. Teachers are appointed by a committee from the Society and the faculty in equal number. A committee was appointed. The granting of such money to students on previous studies a year was considered as leading to some.

The requirements for a medical degree were so arranged that the standard can be advanced as fast as necessary points and preliminary examinations required.

REPORT OF THE BOARD.

The Executive Committee reported, for final action such changes as were made in the by-laws by the adoption of the new charter by the Legislature and that were passed accordingly.

GENERAL REGULATIONS.

The Executive Committee reported several amendments of regulations to the satisfaction of the Executive Committee, and the various departments of medicine were mentioned.

MEMBERSHIP REGULATIONS.

The committee reported a variety of resolutions showing proposed changes which would be made by the Executive Committee from seeking advice of the various departments. This showed the various departments and the fact whether a member of the New York State Society and the various departments.

Reference was made to the various resolutions.

A communication was read by the Secretary in regard to the Society in respect to the Connecticut Medical Congress at Ansonia last

September. A committee was appointed to consider the matter with power to appoint, and afterwards reported the names of Dr. Francis Bacon, of New Haven, and Dr. N. N. Conroy, of New Britain.

TRANSACTING BUSINESS.

The Treasurer's report was read and referred to the Auditing Committee, who reported it as correct, and it was then accepted. There were large donations in New Haven and Fairfield counties, which promoted the acquisition of a working library in the country, and benefited the efficiency of the department very much, so that the credit ought to be paid. Two other counties had similar donations, Hartford and Middlebury, Vermont.

GENERAL MEMBERS.

Dr. A. N. Hall of Garden City, L. I., and Dr. E. Sprague of New York, were nominated for honorary members.

The Secretary then announced the report of the year.

EXECUTIVE SESSION.

The Society was called to order by the President. The Executive Committee in New York reported the following officers for the ensuing year, who were duly elected:

- The President—H. K. Goodrich, M.D., of Vermont.
- The Vice-President—H. S. Pratt, M.D., of Washington.
- The Treasurer—F. H. Edgerton, M.D., of Middlebury.
- The Secretary—C. W. Chamberlain, M.D., of Hartford.

Various standing committees and delegates to our neighboring societies were elected. The delegates to the New York State Medical Society were Dr. S. Turner of Chester and Dr. W. Wood, East Windsor.

REPORT OF THE BOARD.

The committee reported unanimously that Dr. M. S. Parker be expelled.

The President asked permission to make a statement concerning the case, after which a short debate ensued.

The action of the Fairfield County Society was tabled, and Dr. Parker expelled for the same reason, pending the changes before specified.

The following list was then reported by the chairman of the committee appointed last year, Dr. S. D. Stimpson, of New Haven:

A PROPOSAL RELATIVE TO STEWARD PRACTITIONERS OF MEDICINE.

Section 1. No person practicing or endeavoring to practice any of the branches of medicine shall practice or endeavor to practice within this State, unless he possess the qualifications hereinafter required.

Sec. 2. Every licensed practitioner of medicine, in any of the branches or specialties, who desires to practice or endeavor to practice, in any of the cities, towns, or towns of this State shall first procure from the board of trustees, or committees providing a certificate, signed by all or a majority of the members of said board that he or she is a graduate in good standing of a regularly chartered medical college, and is recognized as such by one of the medical societies represented by said board, or by a committee of such society, and that they are the persons named in said diploma or other document offered to prove.

SEC. 3. It shall be the duty of the Governor to appoint at this session of the General Assembly, by and with the advice and consent of the Senate, a Board of Censors, consisting of six persons, two of whom shall be members of the Connecticut Medical Society, two of the Homœopathic Medical Society, and two of the Connecticut Medical Reform Association, respectively. . . .

The remaining sections related to the license tax and method of executing the proposed law.

After considerable debate, it was moved to indefinitely postpone the subject. The principal objections were that it was unwise to license indirectly irregular empirics, some of whom might be able to pass a creditable examination, and that the measure was too partial, and did not reach the greatest evils.

COLLATION AT MERRILL'S.

During the evening a collation was given at Merrill's by the Hartford City Society. Among the distinguished persons present were Dr. W. A. Hammond, of New York, and Dr. Benjamin Cotting, of Boston, the latter an honorary member of this Society.

The occasion was a very pleasant one, the speeches bright and short, the stories telling and well delivered, and the temper happy.

SECOND DAY.

The Society was called to order by the President.

The Secretary read his annual report. The Society now numbers 420, a net gain of twenty-five. There had been fourteen deaths during the year; average age, sixty-two years. One honorary member, well known in all lands, Dr. Jacob Bigelow, had died during the year. There had been forty-three new members admitted, a larger number than in any previous year.

THE PRESIDENT'S ANNUAL ADDRESS.

The President, DR. CARLETON, delivered his annual address—subject:

HONESTY IN MEDICINE.

In commencing, the speaker said that, contrary to the usual practice of self-glorification and that pleasant exchange of mutual admiration which has been the ancient and therefore accepted as an honorable custom of all professional societies to follow at their annual meetings and reunions, he intended to confine himself more to matters of deficiencies in which criticism was needful and censure was merited. In the relation of the profession to the public there was much to be improved, much that furnished no cause for pride and no ground for gratification. Reform, he claimed, was needed in the schools of medicine. Carelessness on the part of the teachers and good-natured pliability on the part of the examiners, he held to be but poor encouragements to the great body of high-minded and honorable practitioners. Such things were diluting the profession with ignorance and inability, and it was no unusual thing to hear educated members of the laity express their fear and distrust of physicians. After referring to the silly jealousies and insincere criticisms to which many practitioners were prone, the speaker turned to the subject of consultation, and said that in those doctors should be honest to each other and to their patients. If there were disagreements, there should be no concealment, no covering of the errors or omission of each other. Dr. Carleton believed that it would be wise to reverse the code, so that the physician called in consultation should first give his

opinion, rather than the attending physician, as now provided in the code. Further than this, there should be no mutual concessions. Continuing, Dr. Carleton said he wished to put himself on record in favor of the fullest liberty of the patient or his friends to change the attending physician for the consulting physician or any other, and especially in the event of radical differences in either diagnosis, prognosis, or treatment, and it should not be held to be unprofessional to take the case under such circumstances.

Doctors should not exaggerate the danger of the disease, nor belittle it, and thus cheat with hopes that never could be fulfilled. The true condition of the patient should never be withheld from friends, although it might be from the patient. The speaker, however, admitted that occasions might arise where a physician must guard his secret to protect the home or domestic peace of the patient. Then he might rightly say whatever he chose to avert suspicion. Dr. Carleton next took issue with the code requirement that professional courtesy compelled one practitioner to visit the patients of another without fee or reward. Many practitioners absented themselves for pleasure merely, and there was no justice in compelling others to do their work. Taking up the subject of medical jurisprudence, Dr. Carleton referred to the tendency of physicians on the witness-stand to meet an unexpected point with theory and guessing, without the courage to confess ignorance. That resulted in confusion to the individual and discredit to the profession. Medical experts should be summoned by the court and examined by the court, and should not be submitted to the badgering of lawyers. The speaker closed with an earnest appeal to all practitioners to be honest in their profession. The true physician should be contented to build up his own character within his own sphere, as a man of knowledge, fidelity, and honor.

The next address was a dissertation by DR. W. R. BARTLETT, of New Haven, on

THE PRINCIPLES OF HYGIENE AND CONSERVATISM IN SURGERY.

This was a lengthy paper, in which the vicious surgical practices of the past were pointed out and the modern improvements described. He dwelt at some length on and noted the best methods to be employed in preparing patients for severe surgical operations, the after-treatment, etc.

The paper was discussed by Dr. Hosmer, delegate from the State Medical Society of Massachusetts; Dr. Lathrop, of the New Hampshire Society; Dr. Cotting, of Boston; Dr. Webster, of Portland, Me.; and Dr. W. A. Hammond, of New York City.

REPORT OF THE COMMITTEE ON MATTERS OF PROFESSIONAL INTEREST.

DR. WAINWRIGHT then reported on matters of professional interest, and complained sharply of the little assistance given the committee on that subject by the profession of the State. Only one-fifth had replied to their inquiries. A better plan would be to send out the questions at the commencement rather than at the close of the year. A good deal of the work that was formerly done by this committee was being done by the State Board of Health much more fully and acceptably, and a report on vital statistics, etc., would be presented by its secretary.

REPORT OF THE STATE BOARD OF HEALTH.

DR. CHAMBERLAIN, the secretary of the State Board of Health, then read his report. It occupied itself with vital statistics, hygienic policy, and like matters

pertaining to that special branch of medicine, illustrating the history of diphtheria, especially during the year, and its close allies, croup and scarlet fever, with considerations of epidemic and endemic forms of disease, with mortality, tables and charts. A series of apparently sporadic nests of diphtheria were described, and its progress and development, when introduced into new districts. The points illustrating the circular of the State Board of Health on diphtheria were especially noted. There were 425 cases in the place of 589. All but 170 of these were in sets of cases large enough to be considered epidemic.

DR. NATHAN MAYER, of Hartford, read an excellent paper on

YELLOW FEVER.

He described the nature of this dreadful disease, and said that experience had shown that there were but two known remedies—calomel and quinine—sometimes one, sometimes the other, and again both. The speaker, in Newbern, N. C., in 1864, treated with calomel only; to every patient in the first or third stages of the disease, twenty to thirty grains, followed three hours later by two ounces of castor oil; the rest of the treatment to be symptomatic, with this exception: no quinine on any account. The conclusions reached by Dr. Mayer were: that yellow fever in the United States generally owed its origin and spread to importation; that the yellow-fever germ, whatever it might be, possessed a vitality which enabled it after years of dormancy to become active under favorable conditions; that the following might be considered favorable conditions of development, viz.: a southern climate; season of great and protracted heat; soil saturated with the products of animal and vegetable decomposition, which was aggravated by being alternately covered by water and exposed to the sun; more or less contact with the bilge-water and filth of ships, whether they communicated with yellow-fever ports or not; the neglect of sanitary measures; a certain state of the atmosphere that was yet an unknown quantity to us, and which might not be demonstrable; a malarial region; and, finally, the presence of unacclimated material. Where these conditions existed in high potency, it was possible for the yellow-fever germ to develop *de novo*. If the carriers of infection met with few or none of the above favorable conditions, the fever was not likely to spread. Consequently, prophylaxis consisted as much in sanitary regulations as in strict quarantine, both together being the *conditio sine qua non* of immunity. As the disease seemed, besides its effects on the blood, to have its local manifestations in the abdominal viscera, chiefly in a disturbance of the liver and stomach, and in later stages of the kidneys, active purgatives formed an essential point of the treatment.

The next paper was by DR. R. S. GOODWIN, of Thomaston, on

ALCOHOL AS A THERAPEUTIC AGENT.

The author enumerated briefly some of the most prominent physiological effects of alcohol on the human system in health, and defined the position which this important drug should take as a therapeutic agent. The paper did not, however, discuss chronic alcoholism or the extensive catalogue of tissue degenerations which that subject introduced. Dr. Goodwin held that alcohol had, in general, received too much enthusiastic and over-wrought praise as a medicine, and that over-stimulation in disease was not a wise or philosophical mode of treatment. He claimed that alcohol should not be given at the same time as nutri-

ents, nor as a febrifuge in febrile diseases, nor to women during the period of lactation. Alcohol, however, might well be employed as a means of sustaining the heart's action during alarming crises of disease, in the crises of fever, in recovery from shock, in the dangerous syncope following violent hemorrhages, in antagonizing the powerfully depressing influence of morbid agents; also in varieties of nervous disorders by virtue of its sedative influence upon the nervous centres, it might indeed sometimes be of more value than other remedies.

The next paper was on

THE INSANE COLONY AT GHEEL,

by DR. A. M. SNEW, of the Asylum for the Insane at Middletown. The colony of Gheel, Belgium, dated back to the seventh century, and had developed into a great system of government care of two thousand of the quiet, chronic insane. An interesting account of the founding of the colony was given, and Dr. Shew then proceeded to describe the treatment. The patients were first received in the hospital, and were then sent out to live and labor with the families resident in the commune. The better class of patients were provided for in the village; but the others lived with the peasants, and worked in the fields with them. Every hamlet contained restraining appliances; but they were seldom used. Excitable patients were at once transferred to Antwerp or Brussels. Dr. Shew, who visited the colony, was not pleased with the system, for the reasons that there was an absence of good medical care, a confusion of sexes, poorly ventilated houses, lack of wholesome diet, unlimited opportunity for the abuse of patients, and defective curative arrangements.

DR. W. A. HAMMOND, of New York city, by invitation of the Society, read a paper on

THE CONSTRUCTION, ORGANIZATION, AND EQUIPMENT OF HOSPITALS FOR THE INSANE.

He contrasted the inhuman treatment of the insane in the past with the kindly and curative methods of to-day, and gave at length his views as to the character and accommodations of buildings to be used for homes of the insane, both the excitable and the quiet. He dwelt at some length upon the asylums of Gheel and Fitz James, and commended the outdoor employment of lunatics as calculated to afford most beneficial effects. He objected to the governmental system of asylums as too close, and claimed that it prevented the proper investigation of abuses. Few asylums are properly equipped; we saw more of methods of restraint than intelligent methods of cure. Dr. Hammond described at length some of the methods of restraint that were employed, and their injurious working, looking at them from a strictly medical point of view. In conclusion, he claimed that the medical fraternity should give more thought to the subject of the cure of the insane, and the management of insane asylums, and manifested a wish that the Connecticut Medical Society would seriously consider this subject in its application in this State.

DR. CARLETON, of Norwich, exhibited a part of a leg-bone, illustrating ununited fracture, and made an interesting statement of the case, which occurred in New London.

By invitation of the Society, DR. FRANK P. FOSTER, of New York, read an instructive paper on the

USE OF VACCINE MATTER TAKEN FROM THE ANIMAL; and DR. R. W. MATTHEWSON, of Durham, a paper on

FIBROUS TUMOR OF UTERUS REMOVED BY LAPAROTOMY.

This closed the readings; and the following voluntary communications were read by title, and ordered published with the proceedings:

"Official Alcohol as a Stimulant," by Dr. D. C. Leavenworth, of New Haven; "Astringents in Diseases of the Conjunctiva," by Dr. F. M. Wilson, of Norwalk; "Perityphlitis," by Dr. E. C. Kinney, of Norwich; "Mortality of the Insane," by Dr. James B. Olmstead, of Middletown; "Registration," by Dr. C. A. Lindsley, of New Haven; "Spasmodic Spinal Paralysis," by Dr. J. H. Trent, of Terryville; "Arsenic Eating," by Dr. P. A. Jewett, of New Haven; "Treatment of the Insane," by Dr. Baker, of Middletown.

The Convention then, at 2.15 P.M., adjourned *sine die*.

The next annual meeting will be held in New Haven.

After the adjournment, the members of the Convention, delegates from other societies, and invited guests, partook of the annual dinner, which was served at Merrill's Café. This was a very enjoyable affair. After the cloth had been removed, brief speeches were made by Governor Hubbard, Charles Dudley Warner, Dr. Hosmer, of the Massachusetts Medical Society; Dr. W. A. Hammond, of New York; and Dr. Cotting, of Roxbury, Mass.; and Colonel Greene, president of the Connecticut Mutual Life Insurance Company. Letters from Dr. Fordyce Barker, of New York; J. G. Batterson, of Hartford; President Pynchon, of Trinity College, and others, were read, expressing their regret that they were not enabled to be present on the occasion. Dr. Wainwright also received, at too late an hour to present it, a letter from Governor Andrews, in which he stated that he could not be present, as he was preparing to start for Washington, D. C., on business connected with the gubernatorial office.

THE AMERICAN ASSOCIATION FOR THE CURE OF INEBRIATES.

Tenth Annual Meeting held in the City of New York, May 13 and 14, 1879.

TUESDAY, MAY 13TH.—FIRST DAY.

THE Association met in the parlors of the Young Men's Christian Association, and was called to order by the President, DR. WILLARD PARKER, of New York. In his opening address the President referred to the magnitude of the study of inebriety, and the increasing interest apparent among medical men all over the country. The confusion of both theory and prevalent opinion naturally followed the first study of all great topics, and was really a hopeful sign. The past year had brought the most convincing proofs that the inebriate-asylum movement was destined to meet the question of inebriety in a more practical manner than any other. Our duty was clear: as long as the laws endorsed the free use of alcohol, so long would there be a necessity for asylums, both inebriate and insane. When the public recognized the necessity of inebriate hospitals, then the need of palace insane asylums would be lessened. He believed he was safe in saying that fully one-third of all our insane might have been saved, had they been placed in inebriate hospitals early in their history. The inebriety from

which they suffered would have been checked before it went on to insanity. The Association was destined to occupy a very wide place in educating the public and developing the laws which controlled the complex disorder. In concluding, Dr. Parker urged that the Association should not spend time in discussing any of the theories urged in opposition to its work.

After some preliminary business, Dr. J. B. MATTISON read a very excellent paper

"ON CHLORAL INEBRIETY."

In the discussion which followed, Dr. PARRISH related a case of a hypochondriac who used opium and chloral alternately, and who made many ineffectual attempts to stop. The withdrawal of these drugs beyond a certain point was attended with severe prostration and violent fever. The doctor had also made the effort, and concluded it was great wisdom to begin again. He mentioned this case as anomalous, and as indicating a condition in which the drug seemed to be demanded for life.

Dr. PARKER had noticed a similar case.

Dr. MASON had seen a case where morphia was used for years, and the slightest increase or diminution would provoke violent symptoms which necessitated a return to the drug. The patient was living and in fair health.

Dr. MATTISON suggested that where opium was used in conjunction with the bromides, the danger of continuing its use was greatly lessened, and in cutting down the use of opium the bromides were most serviceable.

Dr. G. M. BEARD, of New York, had had a large experience in the use of narcotics, and had found that they were very often antidotes one to the other. In very troublesome cases of insomnia, he used always combinations of opium, bromides, alcohol, and other narcotics, and by alternating them he had often accomplished his purpose without any entailment or danger. He thought chloral as a medicine would seldom be followed by chloral inebriety if used in that way. In all cases where chloral was used, it should be watched very carefully.

LOSS OF MEMORY AND CONSCIOUSNESS IN INEBRIETY.

Dr. T. D. CROTHERS, of Hartford, then read a paper upon the above subject, which was a study of six cases of inebriety, in which the patients had total blanks of memory and consciousness while drinking, and yet went about and transacted business, and gave no evidence of that psychical condition. In one of the cases mentioned, the patient, while in that condition, witnessed an assault and murder, and testified clearly the next day before the coroner's jury, and on the third day recovered his mind and had no recollection of it whatever. He was arrested, and was supposed to have assumed that state for the purpose of shielding the prisoner.

Another case was mentioned, of a business man who lost all memory of events while working over his books. Two days after he awoke in a distant city, and all the interval was a blank, although he had made several important business transactions and seemed perfectly conscious of all his circumstances.

The doctor indicated that cerebral automatism was present in all of these cases, and concluded with a mention of some other cases and some of the medico-legal bearings of these cases.

In the discussion which followed, Dr. G. M. BEARD said the cases reported by Dr. Crothers were clearly those of *cerebral trance*, a suspension of some facul-

ties and intensification of others. That was one phase of involuntary life which was rarely studied by physiologists, and was always full of mystery.

Mr. WILLETT mentioned a case of a man who, while drinking, supposed that he was married, and related all the circumstances with great minuteness, offering to go on the stand and make oath to them. The history showed that it was all a delusion; and from that he argued at some length of the danger of accepting the testimony of inebriates, unless verified by other circumstances, in important trials. He would not infer that they wilfully falsified, but the liability to delusion was great.

Dr. MASON was confident that the testimony of drinking men was always more or less unreliable. He referred to a case of a man of excellent character for veracity, but who had made positive statements, and denied them equally as positively the next day. He was drinking when he made the first statement, although apparently conscious of the import and meaning of his words; the next day he was clearer, and had no recollection of his words the day before. The doctor mentioned a second case of a man who was constantly under some delusion when drinking, and yet it was not observed by his friends, and he gave no evidence of any mental disturbance.

Dr. PARRISH thought that such cases were examples of paralysis of memory and will. He had seen many similar cases among the insane and idiotic. The function of memory was suddenly cut off, and the man moved about like an automaton. He might have a fair degree of intelligence left, and yet give no evidence of his real condition. Such cases were full of interest, and were of the greatest practical importance medico-legally.

Dr. ELISHA HARRIS said Dr. Crothers had opened up a new field in his discussion of these cases, and that it threw a flood of light on many of the perplexing problems of the day. They were all types of many criminal cases, where morbid impulses had resulted in morbid cerebration, often traced to inheritance or some exciting cause. The register of memory was so impaired as to be irresponsible. He had seen some remarkable cases where the memory was a total blank. One, of a man who, while drinking, committed a murder, and, when arrested, he recovered his senses, but never could recall the events of the murder in any way. The doctor had seen other cases in which he firmly believed the person had no recollection of any of the events, and had they been well understood, they would not have been consigned to prison. He would not excuse any one for crime which they might have prevented, but these cases should be studied more carefully, and then we should understand the measure of responsibility, and do more exact justice to both the criminal and the outraged rights of society.

Medico-legally, we could not estimate their importance. Inebriety ramified in every neighborhood in the land, and its effects were felt by every section; yet the public were more or less indifferent, and failed to recognize the great fact that those cases should be studied in hospitals, and treated as diseased men. As a measure of economy alone, it would be a great advantage. These cases indicated how wide a field yet remained to be studied, and how many problems of both criminality and inebriety would be solved when we understood them.

The public were awakening to the importance of comprehending inebriety and its practical management.

The Association then adjourned.

WEDNESDAY, MAY 14TH—SECOND DAY.

The Association was called to order by the President.

The first order of business was reports from the Secretary, Dr. T. D. CROTHERS, of Hartford, Conn., of which the following in an abstract:

The discussions of the effect of alcohol on society to day were marked by a vague uncertainty and a changing restlessness, unnoticed before. The increased publication of books, papers, and sermons, advocating many different theories and opinions, together with the temperance revivals which had sprung up in all parts of the country, enlisted the press, and rousing up the church, followed by organized societies pledged to carry on the work (all having one common purpose—the suppression of the evils following the use of alcohol), were the most significant signs of the times, and indicated clearly a great upheaval of opinion, to be followed by a wider comprehension of those evils and their remedies.

The establishing of inebriate asylums in the midst of opposition and credulity had gone on quietly in the wake of that continuous agitation, gathering friends and influence wherever the subject and its wants were realized.

The narrow prejudice and ignorant opposition had only served to bring out more prominently the principles upon which they were founded, and behind all the clamor and sneer there was an under-current of facts (increasing every year), pointing distinctly to those asylums for a solution of the many problems of inebriety. Of over thirty inebriate asylums established in this country during the past quarter of a century, only four had suspended and gone out of existence. Considering that they were all experimental and working without experience or precedent, and without the sympathy and co-operation of the public, their success might safely challenge comparison with any other charity of the age.

It was a well-recognized fact that the asylum treatment of inebriety was more difficult than that of insanity, and had those asylums not met a necessity as imperative as quarantine stations for infectious diseases, or hospitals for the insane, they would have all failed long ago. The early history of insane asylums was marked by many failures and imperfections, but the principles did not change. The conceptions of the work and the application of its principles might be wanting, but the necessity and value was the same. The necessity of hospital treatment for inebriety was established beyond all question. Within two years a very significant movement had begun, which was the commencement of a great revolution of public opinion in regard to asylums.

There had been opened in this country, within this time, over a thousand temporary lodging-houses and eating-rooms for inebriates—places where the poor, homeless victim, after he had signed the pledge, could be taken and cared for until he was able to go out sober and help himself.

Some of those places had five or six beds, others less. Most of them were free. Some charged a few cents, and trusted the inebriate to pay. Many of them were connected with temperance coffee rooms, and were scarcely known. Some of the temperance eating-rooms had the names of benevolent people, who would give a room and bed to any poor worthy inebriate who was making an effort to get well. In those places they recognized the value of physical aid, and the necessity of food and rest, before the diseased will could be restored. The pledge was first given,

then the physical wants were supplied. The comforts of home and food were furnished either free, or at a cost that was merely nominal, and often clothing was also furnished. Conversation, prayer, advice, personal influence of some friend, watching and protection from old associations, and other temporary means, were employed. Many of those places were managed by societies and reformed inebriates, others by women or churches. The Women's Temperance Union and the reform clubs seemed to sustain the most of those places. In some cities single individuals were supporting little homes of this character, and the purpose of all—to shield and protect the inebriate—was one of the fundamental principles upon which inebriate asylums were based. Without any special notice, and almost unknown in the cities and towns where they existed, those initial asylums were rapidly forming public sentiment, and preparing for a larger and more enduring work in asylums properly organized.

The value of one day's restraint in those homes would bring the most positive proof of the greater good coming from a longer time, with more perfect care and attention. If good food and quiet rest would help to overcome the diseased impulse, it was only a step to realize the value of months of such surroundings, and the possibility of permanent recovery. Those homes were rapidly increasing, and following the track of the great revivals, and they were literally the first efforts of the masses to treat inebriety by rational means. From every one would go out an influence that would far transcend the individual good they could accomplish. The public were ripe for some practical methods of reaching this disorder. A small number of asylums were at work like the videttes of an advancing army. Practical men, both in and out of those asylums, recognized the possibility of making all this vast tide of inebriety support itself in hospitals sustained by law and public sympathy. All the indications were unmistakable, that behind the noise and confusion would be seen the reign of law and growth of homes and hospitals that should meet the demands of the inebriate. The medical profession had also agitated the subject, and during the past year over twenty different papers had been written and read on alcohol and its effects on society, before medical societies in this country, and from all sides came the most cheering proofs that the work of the association was scarcely begun.

DR. ELISHA CHENERY, of Boston, then read a paper

ON THE EFFECT OF ALCOHOL UPON OFFSPRING,

in which he showed the effect of alcohol on the blood-corpuscles, with the changes of tissue, and the pathological conditions which followed. It was a very clear presentation of all the latest facts on the action of alcohol, and the heredity of alcoholized condition.

The paper was very ably discussed by Drs. Willard Parker, Parrish, Mattison, Willett, Mason, and others.

DR. GEORGE M. BEARD read a very able paper

ON SOME FORMS OF NEURASTHENIA RESULTING IN INEBRIETY.

REV. JOHN WILLETT followed with a paper

ON ALCOHOL AND ITS ORIGIN AND CHARACTER, AS BOTH A BEVERAGE AND A MEDICINE.

These papers were discussed at some length, after which several papers were read by title and referred to appropriate committees.

INEBRIATE ASYLUMS IN EUROPE.

A very interesting report was made by DR. JOSEPH PARRISH, of Burlington, N. J., of the inebriate asylum movement in Europe.

The following officers were elected for the ensuing year:

For *President*.—Dr. Willard Parker, New York.

For *Vice-Presidents*.—Dr. Albert Day, Boston, Mass.; Dr. B. N. Comings, Conn.

For *Secretary and Treasurer*.—Dr. T. D. Crothers, Hartford, Conn.

For *Secretary for Foreign Correspondence*.—Dr. Joseph Parrish, Burlington, N. J.

For *Committee on Quarterly Journal of Inebriety*.—Dr. T. D. Crothers, Dr. T. L. Mason, and Dr. Joseph Parrish.

ANNUAL MEETING OF THE QUEENS COUNTY MEDICAL SOCIETY.

(Special Report for THE MEDICAL RECORD.)

THE Queens County Medical Society held its Annual Meeting May 27, 1879, at Mineola; DR. BLASDALE, President, in the chair.

Four gentlemen were admitted to membership, and three were reported favorably by the Board of Censors.

DR. J. ORDRONAUX gave a learned address on the subject

"WHAT IS MALARIA?"

saying it was by common consent acknowledged that it could not be defined, it could not be seen, or weighed in scales however delicate, or tested in a retort. It was only known by its effects on humanity, in which it unfavorably complicated other diseases, adding to them the sad result of fatality.

The ancients as well as the moderns had long used amulets, first as charms, and later, pads, enclosing some of the aromatic gum-resins, to keep off or cure diseases by absorption, astutely applying them over the semilunar ganglion and solar plexus. It appeared that they might have the power of attraction, and increasing the positive electricity of the body at night when in its negative and lowest state, supplementing the protective influence the sun exerted by day, and thus buoying up the system against the mysterious, stealthy attacks of malaria.

MIND AND MATTER.

DR. R. P. GIBSON, of New York, by previous invitation read a paper on the above subject, which he treated in a masterly manner, showing much research. He took and well maintained the ground that mind might, in a specially elevated sense, be nourished and vitalized in its attributes by brain nutriment, adapted directly to that end,—saying: "Bones and muscles each require a nourishment differing from one another; so nerve-fibres and brain-atoms may and do require each their different nourishment, and it must be a peculiar refinement of nourishment to be mind or spirit food. It necessitates the choicest selection, the finest discrimination, to attain this mind refinement and vigor; and to accomplish the object of raising an ordinary *sound* mind to a higher plane of capability of action, and that other point of restoring a partially *lost* mind to a sound condition. This alimentation may consist of choice foods containing appropriate constituents, and administering lacking constituents in the concentrated shape of pharmaceutical preparations." He urged the previously raising

the body to the highest standard of health; and, as a prerequisite to both, to eliminate by effective, far-reaching methods the debris and ashes of the system. Thus to attain the ultimatum of a *mens sana in corpore sano*, he emphasized the importance of the use of special systematic local exercises applied chiefly to the chest; to enlarge the chest and increase its mobility, and to strengthen the respiratory muscles, as the means of obtaining an ample supply of air and oxygen; to fully decarbonize and purify the blood and perfect digestion—means by which he has derived much benefit in the treatment of "diseases of the lungs and throat." That he considered a highly important adjuvant treatment, adjuvant and auxiliary to all the remedies and aids so widely in vogue, and with many good results in the medical profession at large.

Dr. Gibson's paper was highly appreciated, and he was invited to prepare another, to be read at the semi-annual meeting of the Society in October.

OVARIAN TUMOR.

Dr. JOHN DAVIDSON reported a case of ovarian tumor; and by the continued use of a saturated solution of chlorate of potassium he made a complete cure.

Dr. WEBB regarded it as impossible, and stated that in a post-mortem case the same quantity of chlorate of potassium produced ulceration of the stomach, ending in perforation of the organ and death of the patient.

Dr. DAVIDSON stated that the patient in question could be seen by any member of the Medical Society, and that she would give the points of her case.

Dr. W. D. WOOD asked Dr. Davidson whether Dr. T. Gaillard Thomas had diagnosed the case as one of ovarian tumor.

Dr. DAVIDSON replied in the affirmative, adding that at the present time no tumor could be found.

Dr. TRASK stated that he did not think the patient's statements should be taken into consideration, and he had never known a case of ovarian tumor cured by the use alone of chlorate of potassium.

RECORD-BOOKS FOR DISEASES.

Dr. BELL stated that he would send record-books gratuitously to the physicians in the county who desired to use them.

Dr. WHITNEY sent a specimen of

"OSSIFICATION OF THE SPLENIC ARTERY."

Dr. BLASDALE exhibited a specimen of

MAMMARY CANCER

which he removed from an aged lady, who made a rapid recovery.

COMPLIANCE WITH THE NEW MEDICAL LAW.

The new medical law, whereby all regular physicians and surgeons are required to register their names, place of birth, residence, and where graduated, in a book kept by the County Clerk, was complied with before Mr. Van Cott, notary.

The following are the officers for the ensuing year:

For President.—Dr. Richard S. Seaman.

For Vice-President.—Dr. Wm. D. Wood.

For Secretary.—Dr. A. G. J. Finn.

For Censors.—Drs. Banks, Fallon, Ludlum, Nadal, Ferrer.

Delegates to American Medical Association.—Drs. Trask and Frye; alternate, Dr. Overton.

Delegate to Kings County Medical Society.—Dr. Whitney.

Delegate to Suffolk County Medical Society.—Dr. Skinner.

Delegate to State Medical Society.—Dr. Bogart; alternate, Dr. Bell.

Unanimously elected.

(Signed)

W. D. Wood, M.D.,

Secretary.

Correspondence.

DOES SUCCESSFUL VACCINATION PROVE THAT SMALL-POX HAS NOT BEEN RECENTLY EXPERIENCED?

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—I am led to ask the above question because of the following experience: On the 26th of March last there came to my office a patient with an eruption upon face and hands, which, from the history, appearance, and odor, I pronounced a mild case of small-pox. He was accordingly quarantined, and, of course, the family with whom he lived. Another physician saw the patient with me the fifth day of the eruption, and did not think of its being else than small-pox. During my service of several years as the quarantine physician of Boston, I saw and treated several hundred cases of this disease. From beginning to end of my relations with the case here mentioned, I never had a doubt but I had a case of small-pox. I think so still. At the end of two weeks my patient obtained "free pratique," and, not having been very sick, and having but one or two pock-marks, he doubted if he had had the disease.

He went to an "irregular" physician first, who told him he had not had small-pox, and to "prove it" vaccinated him. To all appearance the vaccination was a regular course. Several physicians, "regular" and "irregular," saw it, and expressed the opinion that small-pox could not have been experienced recently. One physician, a member of the Massachusetts Medical Society, gave the patient a written statement that he "had not had small-pox within five weeks" (and also very kindly (?) advised him to "sue for damages"). In the mind of the public I am considered to have made a mistake, and my case seems likely to get into court. In "Seaton's Hand-book of Vaccination," page 279, I find that among the soldiers of the British army, not recruits, there were many more successful vaccinations among those who had had small-pox than among those who had neither had small-pox nor had been previously vaccinated. On page 281 of the same work, I find a quotation from Jenner as follows: "Although the susceptibility of the virus of the cow-pox is for the most part lost in those who have had small-pox, yet in some constitutions it is only partially destroyed, and in others it does not seem to be in the least diminished," and on such, vaccination takes "in the most perfect manner."

In Wood's Practice (fifth edition) mention is made of successful vaccinations on those who had had small pox.

I shall be very grateful to any brother physician whose attention may be called to this letter, if he will inform me, either by letter or through the columns of the RECORD, of any experience or literature to the point upon my case. From the fact that some

of my medical friends were surprised to find even a hint that vaccination would "take" after small-pox, I think the subject may be one of interest to others besides myself.

Very truly yours,
C. IRVING FISHER.

HOLBROOK, MASS.

MORTALITY OF SCARLATINA AMONG THE TENEMENT-HOUSE POPULATION.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—Under the above heading, you refer, in THE MEDICAL RECORD of May 10th, to the experience of Dr. D. W. Perham, one of the district physicians to the North-Eastern Dispensary, which would appear to indicate a surprisingly light mortality, and it occurs to me to say that the epidemic of scarlatina which we have witnessed during the past winter, although noted for the very light mortality accompanying the febrile stage has, in very many cases, been followed by attacks of scarlatinal nephritis, in which the mortality has been correspondingly high, if I am to trust the reports of my associates and my own experience. Indeed, it became a subject of remark among many practitioners that they had been unaccustomed to so great a degree of kidney trouble following the recovery of their patients from the febrile stage. This is quite consistent with Dr. Perham's experience in his dispensary practice, since it is by no means unlikely that his cases may have passed from under observation before the symptoms of scarlatinal nephritis became developed.

The fact that scarlatinal nephritis appears to be more common when the eruptive stage is not very intense in character, is mentioned by most writers, and has become an accepted belief.

F. A. CASTLE.

NORTH CAROLINA BOARD OF HEALTH.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—In your issue of the 26th April you make some complimentary remarks about the North Carolina Board of Health Law, and say that, "but it is not given any power in connection with licensing or regulating medical practice, as is done in some of the Western States." Very true! But North Carolina has had a "State Board of Medical Examiners" since 1859. It is an auxiliary of the State Medical Society, as is the State Board of Health; and as there has been little or no opposition to it, the Board has increased in strength and usefulness, and is the oldest licensing body, independent of a college, in the South.

Yours very truly,
THOMAS F. WOOD.

WILMINGTON, N. C., May 28, 1879.

NEURITIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—The paper of Dr. Putzel, in the RECORD of April 26th, is a valuable addition to the clinical evidence of neuritis migrans. Until a larger measure of pathological evidence shall be adduced, any professional and accurate opinion of the merits of the discussion between Feinberg on the one hand and Rosenbach on the other will be impossible. I have been

able to demonstrate quite satisfactorily, at least to my own mind, that irritation of the sciatic nerve in the rabbit destroys the electrotonos of the nerve-current, so that it will not respond to the galvanic current, and will give but feeble reaction to the induced current. This is natural when we remember that it is the galvanic current which causes that modification of nerve-current to which the name electrotonos has been given. Between the anode and cathode of the nerve so irritated there was very slight manifestation of electric sensibility; neither were there manifest any of the responsive symptoms of the healthy nerve in the extra-polar region, when either or both electrodes were applied over the seat of the irritation. Beyond the focus of irritation the nerve-current was normal for two days. On the third day the extra-polar region exhibited signs of insensibility to both currents for a distance of about five mm., while the portion primarily acted upon by the caustic showed evidences of degeneration. This condition extended to the muscular branches and greatly modified the tonicity of the muscles supplied by them. On the seventh day the rabbit was partially paralyzed in both hind legs; there was no electro-muscular contractility and but little electro-muscular sensibility. Death on the twelfth day. Except upon the theory of "reflex inhibitory action" it would be difficult to account for certain cases of paralysis. I have met with an instance which would seem to bear out the theory of reflex paralysis. A married woman, forty-seven years old, suffered with an acute attack of congestion of the cervix uteri, and coincidentally with it there was total loss of power—complete paralysis of the lower extremities. The congestion yielded to appropriate treatment, and with its subsidence the paralysis entirely disappeared, and she has never since that time been similarly afflicted.

HORATIO R. BIGELOW, M.D.

WASHINGTON, D. C., 1009 12th Street, N. W.

Obituaries.

JOHN THOMSON DARBY, M.D.

DR. DARBY, late Professor of Surgery in the Medical Department of the University of the City of New York, died on Monday, the 9th inst., after a lingering illness. He was born at Pond-Bluff Plantation, St. Matthew's Parish, S. C., on the 16th of December, 1836, and was a descendant from English colonial residents of the province of the Carolinas. His early education was acquired at Mt. Zion and South Carolina colleges. He pursued his first regular course of medical lectures at the Medical College of Charleston, and graduated as a doctor of medicine at the University of Pennsylvania in 1859, having been a private student of Professor Leidy. After graduating he became an interne of the St. Joseph and Philadelphia hospitals, gave private courses of instruction on surgery, and was made demonstrator in the Chant-Street School of Anatomy, then conducted by Dr. D. H. Agnew. He practised medicine in Philadelphia until the breaking out of the civil war, when he returned to his native State, and at once was appointed surgeon in the Confederate army. He served in the field from May, 1861, until the surrender, in May, 1865, having held, in succession, the position of surgeon to the Hampton Legion, and chief surgeon and medical director in various commands of the armies of Virginia and Tennessee. During the war he was sent

to Europe on a mission connected with the Medical Department of the Confederate States, where he devoted four months to a general study of the hospitals of London and Paris. At the close of the war he returned to Europe, and pursued his studies, both in the hospitals of Great Britain and of the Continent. He served as a volunteer field surgeon in the Prussian army during the German war of 1866. In 1868, while still absent in Europe, he was elected to the chair of Anatomy and Surgery in the University of South Carolina, and, on his return, established himself in Columbia. He subsequently resigned this position, and, in 1873, accepted the professorship of Surgical Anatomy in the Medical Department of the University of the City of New York. In the following year he was elected Professor of Surgery in the same institution, which position he held until a short time before his death, when he was made Emeritus Professor. At the time of his death he held the position of Visiting Surgeon to Bellevue and Mt. Sinai Hospitals of New York, and was a Member of the Medical Society of the County of New York; the New York Academy of Medicine; the Academy of Sciences, Philadelphia; Permanent Member of the American Medical Association; and several local medical societies. He was also ex-President of the State Medical Association of South Carolina. Dr. Darby was a genial gentleman, and a favorite medical teacher. His skill as a surgeon was fully recognized by his colleagues, and by those who had opportunity of witnessing some of the more brilliant of his operations. Among his contributions to medical literature the more prominent are: "A Thesis on the Anatomy, Physiology, and Pathology of the Supra-Renal Capsules;" "Campaign Notes on the German War of 1866;" "Horse-hair as a Ligature and Suture;" "Liquid-Glass as a Surgical Dressing;" and "The Trephine in Traumatic Epilepsy."

FRANCIS FONTAINE MAURY, M.D.

On Wednesday evening, June 4th, at about half-past nine o'clock, Dr. F. F. Maury, a very prominent and talented Philadelphia surgeon, died at his late residence, No. 1218 Walnut Street, Philadelphia, in the thirty-ninth year of his age, after an illness of over two months' duration, the immediate cause of his death being congestion of the lungs. Between two and three months ago Dr. Maury accompanied the late Colonel Samuel S. Moon on a trip to the Hot Springs, Arkansas, where Col. Moon went for his health, Dr. Maury travelling with him as medical adviser. When he left the city, Dr. Maury's wife was in perfect health, but was seized with acute peritonitis during his absence, and died just before he returned home. The husband was overwhelmed with grief at this sudden loss, and soon afterwards was taken sick himself, and continued to grow worse until he was seized with the attack which carried him off.

Dr. Maury was born in Danville, Ky., on the 4th of August, 1840. His father was a clergyman, and was born in Virginia, and descended from a French Huguenot family. The deceased was educated at Centre College, Danville, and graduated in 1859. He attended his first course of lectures at the medical department of the University of Virginia, but went the next year to Philadelphia, and graduated at Jefferson Medical College in 1862. Since his graduation, Dr. Maury has always lived and practised in Philadelphia. He was the first surgeon in the United States to perform the operation of gastroto-my.

Dr. Maury edited *The Photographic Bureau of Medicine and Surgery* for two years, and published a number of reports of medical and surgical cases. He was surgeon to the Jefferson Medical College Hospital, and it was largely through his efforts that this hospital was established. He was also one of the surgeons to the Philadelphia Hospital, and during the war was Surgeon-in-chief of the United States Army Hospital at Twenty-fourth and South streets, Philadelphia. He was lecturer on venereal and cutaneous diseases in Jefferson Medical College, and was also a fellow of the Philadelphia College of Physicians and Pathological Society.

At the time of his death Dr. Maury was surgeon to the First City Troop, of Philadelphia, and had held that position for some time. He served as coroner's physician several years ago. Dr. Maury came to Philadelphia as an entire stranger, but his success in his profession was remarkable and immediate. His specialty was venereal diseases. The deceased leaves two young children.

THE AMERICAN NEUROLOGICAL ASSOCIATION.—The American Neurological Association will hold its Fifth Annual Meeting, in Municipal Hall, 67 Madison Ave., New York city, beginning at 2.30 p.m. Wednesday, June 18th, and the profession are invited to attend the meetings of the Association on the 18th, 19th, and 20th.

AN ACT FOR THE RELIEF OF DR. WILLIAM A. HAMMOND.

WAR DEPARTMENT,
WASHINGTON CITY, May 12, 1879.

SIR:—I have the honor to enclose herewith draft of a bill to amend an act entitled an act for the relief of William A. Hammond, late surgeon-general of the

army, approved March 15, 1878, and to recommend the passage thereof. I have the honor to remain,

Your obedient servant,

GEO. W. McCRARY,

Secretary of War.

Hon. Samuel J. Randall, Speaker House of Representatives.

Be it enacted, etc., That the act entitled an act for the relief of William A. Hammond, late surgeon-general of the army, approved March 15, 1878, be, and the same is hereby amended by adding to the first section thereof the following proviso: *Provided,* That the President may in his discretion consider any newly discovered evidence, or any evidence improperly excluded upon the trial of said Hammond touching the truth or the falsity of the charges upon which he was tried.

INTESTINAL OCCLUSION CURED BY INJECTIONS OF SELTZER-WATER.—Dr. Prunac adds another to the cases of volvulus already reported as cured by rectal injections of Seltzer-water. The patient, a man seventy-five years of age, had suffered for three months from severe diarrhoea, when the passages suddenly stopped, and for five days he passed neither faeces nor gas per anum. The other symptoms were fecal vomiting, frequent hiccough, anxious facies, cold, clammy perspiration, small, quick pulse, and intense tympanitis with consequent dyspnoea. After the failure of several other methods of treatment, an oesophageal catheter was introduced almost its entire length into the rectum, its external opening was fitted to the tube of a siphon of Seltzer water, and the contents of three siphons (about two quarts) were injected into the intestine. This was followed by the injection, by ordinary means, of another quart of the water. A few hours later the obstruction gave way, and large quantities of fluid and solid fecal matters and gas were passed per anum. The symptoms at once began to improve, and after five days the recovery was complete. Dr. Prunac thinks the employment of the siphon preferable to simple injections of gaseous water; its advantages are of a more forcible projection of the fluid and complete retention of its gaseous constituents.—*Gazette des Hôpitaux.*

POISONING BY CYANIDE OF POTASSIUM.—Dr. Warneck, of Kiel, reports the case of a man, who took, with suicidal intent, nearly 45 grains of cyanide of potassium. The principal symptoms were immediate loss of consciousness, vomiting of food and of a fluid having the odor of bitter almonds, profound coma, viscid perspiration, coldness of the extremities, cyanosis, convulsive twitching of the eyes, dilatation of the pupils, abolition of motion, sensation, and reflex excitability, irregular and superficial respiration, small, irregular pulse, 120 to the minute, fall of the temperature to 97.2° F., and involuntary micturition. Dr. Warneck injected half a drachm of sulphuric ether subcutaneously, and then washed out the stomach until the water used no longer had any odor of bitter almonds. The condition of the patient, however, rapidly became worse, the respiration becoming more irregular and the pulse smaller, despite repeated injections of ether. He was then placed in a bath at 91½°, and iced water was poured over the head and the nape of the neck. Every time the water was poured on the head, the patient drew deep inspirations. Gradually the respiration became deeper and more regular, and all the dangerous symptoms disappeared after a bath of one hour. Convalescence was rapid, but a general muscular weakness and an impairment of speech persisted for a long time.—*Lyon Medical.*

"THE PHYSICIAN AND SURGEON."—We have just received the first number of a new Western journal, entitled *The Physician and Surgeon*, and edited by V. C. Vaughan, M.D., Ph.D. It is to be a monthly, and devoted to *practical* medicine and surgery. There are five associate editors. This first number contains several interesting original articles, and the abstracts are well selected. It is well printed on heavy paper.

"THE CHEMIST AND DRUGGIST," of Philadelphia, has changed its title and publishers: the former is "*The Monthly Review of Medicine and Pharmacy*;" the latter are Keasbey and Mattison.

THE CASE OF DR. GROUX, THE MAN WITHOUT A STERNUM.—Dr. Charles Jewett has an article, in the Proceedings of the Kings County Medical Society, on the anatomy of Dr. E. A. Groux, lately deceased. For many years the latter went from college to college exhibiting his chest minus a sternum, and an apparent ability of voluntarily suspending the heart's action.

PYROGALLIC ACID IN HÆMOPTYSIS is highly recommended in hæmoptysis, metrorrhagia, and other internal hemorrhages on account of its small dose, its not deranging the stomach as other remedies do, because it is easily taken and has no disagreeable after-taste. It is asserted to be more rapid and certain in its action than gallic or tannic acid, ergot, pil. plumbi cum opio, etc. It is soluble in water or spirit.

SALICYLIC ACID IN DYSPEPSIA.—Prof. Kolbe, of Leipzig, took gr. xv., in divided doses, daily for dyspepsia during *nine months*, not only without any unpleasant symptoms or album in his urine, but with the effect of curing his dyspepsia and improvement in general health.

DANGEROUS COLORS IN WALL-PAPER.—Mr. L. Siebold, of London, found arsenic in 50 out of 60 samples of wall-paper of various colors, blue, red, brown, pink, etc. This fact may assist us in explaining the cause of many slight attacks of functional derangements in children which so puzzle the mother and doctor.

CHINESE ANATOMY.—The Chinese physicians are not necessarily skilled anatomists or accomplished physiologists, since, at a recent inquest at San José, Dr. Cog Fy, the attendant physician upon the deceased, to the question: "How many lungs has a man?" replied: "Seven." He further stated there are five holes in the human heart, and that the function of the latter is "to catch air in."

THE MEDICAL REGISTER of New York, New Jersey, and Connecticut for the year commencing June 15, 1879, has appeared, Dr. William T. White, editor; G. P. Putnam's Sons, publishers. In addition to the usual material, the present volume contains valuable statistical tables. The book reflects credit upon the editor, upon the Medico-Historical Society, and upon the publishers.

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, June 21, 1879.

THE NATURE, CAUSES, AND PREVENTION OF THE INFECTIOUS DISEASES.

At the last meeting of the London Pathological Society, the committee appointed to inquire, at the suggestion of the late Dr. Murchison, into the nature, causes, and prevention of the infectious diseases known as pyæmia, septicæmia, and purulent infection, made its report. The report was voluminous, and embraced observations made under three heads: etiology, semciology, and pathology. The deductions reached relating to the etiology of pyæmia and septicæmia, and based on statistics taken from ten large London hospitals, are very interesting. The committee accepted the recognized distinction between pyæmia and septicæmia, consisting in the presence of metastatic abscess in the former only, and first directed their attention to the subject of artificial septicæmia. For this form of septicæmia they use the term "septic intoxication," and, although their calculation has been made only approximately, they believe that for its development introduction of as much as two or three ounces of putrid serum into the blood at the same time is necessary. To permit this, two conditions are requisite: first, opportunity for the accumulation of fetid discharge; and second, a large absorbing surface. This is the form attended by the greatest mortality, and doubtless obtains in many cases of rapid death after ovariectomy. The morbid anatomy of this form is represented chiefly by softening of the spleen, subserous hemorrhage, and fluidity of the blood. As far as could be ascertained, the effects produced by infection from one patient to another, ordinary septicæmia, were very nearly the same as those produced by rapid septic intoxication, except that they are spread over a longer period of time. Koch, however, first showed that there is an anatomical difference between them, and that in all cases of ordinary septicæmia—septic infection—the blood contains

organisms. The report contained the detailed histories of twenty-nine cases of septicæmia, of which two were cases of rapid septic intoxication.

PYÆMIA.

While the committee retained the ordinary definition of the term pyæmia in the 127 cases reported, they make no fewer than eight subdivisions of this form of blood-poisoning. They base these subdivisions mainly upon the situation and relations of thrombosis and softening clots to secondary abscesses, and thus give separate places to the pyæmia following acute necrosis and ulcerative endocarditis. This seems to us like an unnecessary refinement, and has the appearance of a distinction without a difference. With reference to organisms, they were found in nearly all the cases in which the blood was examined, but there was no constant proportion nor constant uniformity of size and shape. The committee did not attempt to trace relations between the different forms described, simply state the facts, and state that they believe the facts justify the conclusion that the organisms are evidence of the existence rather than the cause of the blood-poisoning.

The histo-pathological investigation was remarkably thorough, and was attended by a singularly uniform result. The spherical form of organisms—micrococci—were present in large numbers in all parts, but bacteria were found in only two cases, and, in one of those, they were probably due to decomposition. There is, doubtless, some explanation for the fact that bacteria were found in the blood in many cases during life, while in only one case were they found after death, but like wise men the committee did not give an expression of opinion upon this point. The report is doubtless the most complete that has been offered upon the subject of pyæmia and septicæmia, and will prove a most valuable aid in the future study of infectious diseases.

THE REPORT ON THE STATE INSANE ASYLUMS.

THE Senate committee, to inquire into the condition of the insane of the State, after a certain amount of investigation, reported back that the asylums were in excellent condition, particularly the State Lunatic Asylum, and that the wanton attack upon them was unworthy of the profession and degrading to the dignity of the State. The spirit of the report seems to be to bring out prominently all the favorable facts, and ignore everything of a contrary nature.

This result of the committee's investigations was doubtless due in part to the powerful political influence of asylum superintendents, and partly to the inefficient manner in which the petition for investigation was framed and supported. For this document covered only part of the ground that might have been taken, and it expended much of its force upon petty complaints against asylum superintendents and mim-

portant details of management. The whole investigation was so interwoven with personal and political feelings—so much more a fight than an inquiry—that its ever having been undertaken is much to be regretted. Although it may produce a certain amount of benefit by inciting those in charge of asylums to more vigilance in discharge of their duties, its general effect will be to give the public the impression that everything is as good as it can be in connection with the State insane, and to discourage further attempts at reform.

We hope it will not be forgotten, however, in spite of the eulogistic statements of the committee that there are many very radical defects in the management of our insane, and we believe that some of our asylum superintendents are not only cognizant of that fact, but are desirous that changes should be made. No amount of partisan rhetoric can disguise the fact that though the State has spent four millions in extravagantly designed insane asylum buildings during the past ten years, there is, nevertheless, almost as much overcrowding now as ever; further, that nearly two-thirds of the State insane are still in badly managed county asylums and poor-houses; that early and efficient treatment of the insane is generally impossible; that the asylums have, as a rule, insufficient attendance and too much physical restraint; that, in fine, with our insane every year increasing, and with the spasmodic erection of costly and unwieldy asylums furnishing no adequate relief to this increase, we need some radical changes and reforms in the matter in question. The declarations and fulsome eulogies which resulted from the recent incomplete investigation should not blind the public to these facts.

Senator Goebel, who quoted the praises, by the English alienist, of the State Lunatic Asylum, forgot entirely to quote the scathing criticisms from the same person upon other State institutions where, perhaps, he had not been entertained so liberally.

THE NATIONAL BOARD OF HEALTH.

The National Board of Health has been in session in Washington during the past week. Regulations were adopted with regard to maritime quarantine, making it the duty of consular officers to keep themselves thoroughly informed as to the existence of infectious diseases in the neighborhood of their stations, and requiring the master of every merchant ship sailing from a port where there is such an officer to procure a bill of health that shall be either clean or foul, according as the disease does or does not exist at said port. Provisions have also been made for care in excluding from ships passengers or goods suspected of being infected, and for proper attention to cleanliness. These are substantial advances towards an effectual quarantine against such diseases as cholera,

yellow fever, small-pox, typhus fever, and others of like character.

The National Board of Health, under the recent law, is also required to co-operate with State and municipal organizations, and recommendations have been made looking towards an effective system of internal quarantine. We trust there will be no conflict between authorities upon questions, the proper decision of which is so important to the common weal. It seems to be accepted that a national quarantine can be established that will not in any way interfere with the varying interests of the ports along the entire Atlantic coast, and yet prove an effectual barrier against an invasion by epidemic diseases. We hope that the most sanguine expectations of the Board and of the people will be realized by a careful execution of the present law.

THE ABUSE OF MEDICAL CHARITY.

We publish this week the last discussion held on the above subject before the Medical Society of this county. Some plain facts have been given, and so long as the abuse continues to exist and to increase, it should not be forgotten by the profession and by the public. An important point made in the paper read by Dr. Sturgis, and sustained by several who participated in the discussion, was that physicians were largely, if not entirely, responsible for this ill-conditioned nuisance. If the putrescence is in our own household, there should be sufficient vitality and sanitary science in the profession to remove it, or at least so correct its foul odor that it will not rise as a stench to the nostrils of honest philanthropic men and women. If genuine honesty of purpose can be instilled into the hearts of all who now hold, as well as those who, while under the excitement of the last emotion to do charity, make application for dispensary positions, and we believe there is room for the medicament, it will do much towards suppressing the growing evil. The question has its knotty points; but there is no doubt that an educated public opinion, fortified by a sturdy declaration on the part of the medical profession that, having rights, they dare to maintain them, can establish a permanent and radical reform. The remark incidentally made by one of the speakers, that the profession and the city would be better off were all the dispensaries wiped out, is worthy of candid consideration. The resolution adopted by the Society is a favorable step, and we hope its existence will be daily remembered.

MEDICAL CERTIFICATES.

STILL they come! Organisms from Bilbo! Last of all, a certificate attached to a lager-bier advertisement, originating at the capital of the State, and signed by three gentlemen of recognized good standing in the medical profession.

The healing properties of the Richfield Springs are embalmed in the memories of thirty-two medical gentlemen from New York, Philadelphia, Boston, and other cities, deservedly eminent in their profession, and their names appear in a circular which goes wide spread asking that bread be cast upon their waters. There they are, and if the trouble is in your eye or ear the virtue of the water can be attested; if you have a friend who is insane, he need not grow gray with the malady, for the doctor has been to the pool; if your respiratory organs are weak, lung doctors can suggest where they may be strengthened; if large doses irritate your gastric mucous membrane, and disturb the tranquillity of your conscience, the small-pill man can transform the sombre covering into a delicate *gray* robe; if the promontory on your face has met with misfortune and sadly needs a plastic operation, you can be posted in that particular; and if you belong to the class, so numerous, who suffer from general debility, staid general practitioners can guide your feet to the healing fountains.

Saratoga, one of the pioneer watering-places, disliking to be outdone by honest competition, sends greeting to the world, and throws to the breeze her banner bearing the names of those who can tell how an easy *delivery* from the thralldom of disease can be effected.

While we do not care to look over the precipice, and are not yet prepared to believe that the time will come when it will be necessary for physicians of eminence to placard their backs with the plain words, "Commit no nuisance under penalty of law," we fear there are many in our ranks who either intentionally or indifferently are hastening the dawn of that unfortunate era. What a conglomeration of counsel is represented by the names! As we scan the list a ray of hope is obtained only in the thought that, in this, as in certain other propositions, "there is safety in numbers." There are allopaths and homeopaths, wolves in sheep's clothing and goats by the name of scape; the seer and the verdant, with portraits at full length, reflected either in the beer-vats of Albany or the delicious medicinal waters of Richfield and Saratoga.

A SUBSTITUTE FOR HANGING.

Protestations against the present method of executing criminals have been frequently and urgently made; but they have not as yet secured much attention from our legislators. The difficulties of changing a long-established practice are immense, especially when such practice is one that no person can fail to feel some delicacy in claiming a personal interest in. In addition, it has generally been thought, and we believe rightly, that most of the cases where death has failed to take place at once have been due to carelessness and lack of skill on the part of the executioner,

and not the fault of the method itself. The subject has, however, been considered recently, with more than usual care, by Dr. Packard, of Philadelphia; and this gentleman urges, as the result of his examination, that death should be produced by carbonic oxide. He proposes that the victim should be placed in a small, air-tight room; the air should then be rapidly replaced by carbonic oxide gas, when death will take place in the most rapid and painless manner known to science. In ten minutes, indeed, the corpse can be removed from the room and identified by the jury. The process, as compared with those cases of hanging, not very frequent, where the death-struggle lasts for five, or even fifteen minutes, certainly seems superior. After all, however, when hanging is properly done there is scarcely any practicable mode of extinguishing life that has so many fatal elements in it. According to Hoffmann, of Vienna, there takes place when the noose is suddenly tightened a complete closure of the carotids and jugulars, which arrests the circulation in the brain; a pressure on the pneumogastrics, which may even of itself cause unconsciousness; an occlusion of the trachea, and possibly a rupture of the odontoid ligaments, and pressure on the medulla. And all these are certainly enough. M. Fleischmann, by experiments on himself, proved that in the act of hanging there was no pain, but merely, at first, a ringing in the ears, then a flash of light, and then unconsciousness. Various investigations, therefore, seem to indicate that hanging may be made the most humane and effective method of execution, if properly carried out. But it is certain that those who superintend the matter in our country need more knowledge and skill in regard to the application of this judicial process.

Reviews and Notices of Books.

A GUIDE TO THE QUALITATIVE AND QUANTITATIVE ANALYSIS OF THE URINE. By DR. C. NEUBAUER and DR. J. VOGEL. Translated from the seventh German edition by E. G. Cutler, M.D.; revised by E. S. Wood, M.D. pp. 551, Svo. New York: Wm. Wood & Co. 1879.

A work that has already reached seven editions in the original, and has been translated into other European languages, hardly requires recommendation now that it again appears in an English form. There are but two exhaustive treatises on this subject extant: that of Thudichum, which has been before the profession for twenty years or more, and the one now before us. The work is divided into two main parts; the first by Neubauer, which treats the subject from a chemical standpoint only, and that by Vogel, which considers the semiology of the urine, and points out the relations between the observed chemical changes and the alterations of the system that have given rise to them. In other words, the inquirer is enabled to ascertain not only the abnormalities of the urine, but also the pathological states of which they are the indications.

The first part of the work is divided into three por-

tions, embracing the physical and chemical properties of normal urine, the normal and abnormal constituents of urine with the methods for their detection and isolation, urinary sediments, and accidental and medicinal constituents. A hundred pages are then devoted to the methods for the performance of qualitative estimations; these are followed by thirty pages devoted to the systematic analysis of the urine, including the recognition of sediments under the microscope and methods for their permanent preservation.

Dr. Vogel's contribution to the work embraces two hundred pages and contains a large collection of valuable matter that would otherwise have to be sought in the pages of many books. The work is embellished with three lithographic plates, representing the microscopic appearances of the urinary sediments and a chromo-lithographic chart or color table of the urine, together with a colored spectrum showing the blood-bands. The paper is excellent and the type large and clear, and the copy before us is bound in a reddish leather that forms an agreeable contrast to, and change from the light colored sheep bindings with which we have so long been familiar. It also appears to be a stronger leather than that in general use, and impresses us as being more durable.

THE BRAIN AND ITS DISEASES. Vol. I. SYPHILIS OF THE BRAIN AND SPINAL CORD. THOMAS STRETCH DOWSE, M.D. London: Baillière, Tindall & Cox. 1879.

The little work of Buzzard has been hitherto the only book in the English language dealing with nervous syphilis alone, and as this work was fragmentary and appeared some time before the translations of Heubner, it was necessary to consult French and German authorities, if extended information was needed. Dr. Dowse's volume is therefore a welcome addition to this branch of neurological literature. It is divided into eight chapters, the first of which treats of the "History and Nature of Syphilis," but a photograph of syphilitic disease of the rectum is presented which strikes us as strangely out of place in a book which takes for its subject an organ situated at the other end of the body. Subsequent chapters are devoted to the diagnosis of "Syphilis of the Brain and Spinal Cord; Sympathetic System of Nerves; of the Peripheral Nerves," etc. Chapter V. deals with "Treatment," VI. with "Hereditary Syphilis," VII. with "Syphilitic Epilepsy," and VIII. with "Pathology." Leaving the first chapters, which contain but little that is new, we turn our attention to those upon diagnosis, which are exceedingly practical, and present cases which very appropriately illustrate the subject. This criticism, however, does not apply to "Diseases of the Sympathetic System," for Cases X. and XII. show absolutely no peculiar characteristics, and would pass equally well for examples of ordinary dysæsthesia or hypochondriasis, which might be due to any, or even no cause whatever.

The article on "Syphilitic Epilepsy" is very full and ably written, and the chapter upon "Pathology," though not so complete as it might be, shows, nevertheless, original research. We regret that more attention has not been paid to the mental changes so peculiar to certain forms of syphilitic disease of the brain.

The typography of the book is good, and the paper is excellent. The illustrations, with the exception of that already referred to, and a woodcut on page 72, are quite good. The latter cut is exceedingly bad and shows nothing whatever.

A CLINICAL TREATISE ON DISEASES OF THE LIVER. By DR. FRIED. THEOD. FRERICHS, Professor of Clinical Medicine in the University of Berlin, etc. In three volumes. Vol. I., translated by Charles Murchison, M.D., F.R.C.P. New York: Wm. Wood & Co., 27 Great Jones Street, 1879. Wood's Library of Standard Medical Authors.

The English edition of Frerichs on the liver, consisting of two volumes, has been divided into three volumes, which will appear in the series constituting Wood's Library of Standard Medical Authors. The present volume is the first, and contains the historical account of diseases of the liver, the definition of the dimensions and weight of the organ, physical diagnosis, the chapters on icterus, acholia, acute and chronic atrophy, and the fatty liver. The established reputation of the original work places the present volume, and those which are to follow, beyond special criticism. The age of the book entitles it to reverential consideration at least, and for that reason it may have lost some of its pristine excellence as a standard authority upon the diseases of the liver. The date of the author's preface is 1858, and that of the translator's preface is 1860. Doubtless very much has been learned concerning diseases of the liver since those dates, and the query might arise whether either a later edition or some more recent work could not have been turned into this channel with a larger acceptance by the profession and a greater profit to the publishers. However, it is a good book, and in its present form will be a most valuable addition to the library of the general practitioner.

Vol. II. contains chapters on the pigment liver; hyperæmia of the liver and its consequences; inflammation of the liver, its various forms and consequences; the waxy, lardaceous, or amyloid degeneration of the liver; and hypertrophy of the liver. To these is added an appendix, and the whole embraces 228 pages. It has a frontispiece on which are illustrated a syphilitic fibroid nodule, alveolar cancer, cavernous tumor, and hepatic cells in a state of waxy degeneration.

Vol. III. contains chapters on pathological new-formations in the liver—hepatic tumors; diseases of the blood-vessels of the liver; and diseases of the biliary passages. To these is added an appendix, and the whole embraces 239 pages.

To this volume is also added a general index for the three volumes. It also has a frontispiece on which are illustrated crystals of bile-pigment crystalline forms of carbonate of lime from the mucous membrane of the gall-bladder, and gall-stones of a variety of shapes.

MODERN SURGICAL THERAPEUTICS: a Compendium of Current Formulæ, Approved Dressings, and Specific Methods for the Treatment of Surgical Diseases and Injuries. By GEORGE H. NAPHEYS, A.M., M.D. Sixth edition. Philadelphia: D. G. Brinton, 1879. 8vo, pp. 605.

We are not surprised at the popularity of this work, as it was guaranteed from the start by the plan which was adopted and by the thoroughly practical information which it contained. Between thirty and forty pages have been added to the work, and no pains seem to have been spared to bring it up to date. We are informed in the preface that the present edition "is called the sixth so as to make it synchronous with the sixth edition of Naphey's Therapeutics, as it is the development of the surgical part of that work; as a separate volume it is in its second edition." The work is of great value as one of ready reference for the general practitioner.

LECTURES ON PRACTICAL SURGERY. By H. H. TOLAND, M.D., Professor of Principles and Practice of Surgery, Medical Department of University of California. Second edition. Philadelphia: Lindsay & Blakiston, 1879. 8vo, pp. 518.

This book comprises a course of lectures delivered at the medical school, in which the author is Professor of Surgery. As such it is quite complete, embodying the author's views upon many of the departments of surgery, and will no doubt be valuable to the pupils of the university for whom it is more particularly intended. There have been but few changes from the first edition, except the addition of an extra lecture, and an account of two more cases of aneurism.

THE TRANSACTIONS OF THE AMERICAN MEDICAL ASSOCIATION, Vol. XXIX. Philadelphia, 1878. 8vo, pp. 1,145.

THE present volume, which is an unusually ponderous one, represents the doings of the Association at its meeting in Buffalo last year. It contains thirty-nine original papers on various subjects connected with the different departments of medicine and surgery, added to which is the prize essay of Dr. John A. Wyeth, which adds a special value to the volume. The different papers are of great interest, there being scarcely two or three that would not repay careful study; but Dr. Wyeth's Essay is an interesting work in itself, and comprises an exhaustive history of the surgical anatomy of the common, external, internal, innominate, and subclavian arteries. In this essay there is an analysis of 173 dissections of the surgical regions of the neck, and a collection of 1,198 cases in which the results of deligation of these vessels are given. To the practical surgeon this essay is an invaluable contribution, and we are pleased to see that, being published in separate form, it is saved from being virtually lost to all but members of the association.

ESSAYS ON SURGICAL ANATOMY AND SURGERY, etc., etc. By JOHN A. WYETH, M.D. New York: William Wood & Co., 1879. 8vo, pp. 261.

WHILE we say that the volume is on the whole an interesting one it is the more to be regretted that its field of usefulness is so small, and that by a resolution of the Association papers read before the said body cannot be given to the medical world through the medical journals. The manual is as usual well printed, and is bound in the style uniform with previous editions. The present one is well worth the standard price of \$5.

A TREATISE ON THERAPEUTICS, comprising Materia Medica and Toxicology, with Especial Reference to the Application of the Physiological Action of Drugs to Clinical Medicine. By H. C. WOOD, JR., M.D., Prof. Materia Medica and Therapeutics, etc., University of Pennsylvania. Third edition, revised and enlarged. Philadelphia: J. B. Lippincott & Co., 1879. 8vo, pp. 719.

It is unnecessary to say to any student of materia medica that the work of Prof. Wood is a standard, and that, as an exposition of the physiological action of drugs and its application to clinical medicine, it is unsurpassed. The present edition is brought up to the present state of our knowledge by numerous alterations and elaborations of the text, and by the addition of new articles, as for instance, those on salicin, borax, thymol, etc. The articles on jaborandi and salicylic acid have been virtually rewritten. These necessary additions have increased the size of the work by fifty

pages. The success of the work is well merited and reflects credit upon its studious and accomplished author.

HEALTH, AND HOW TO PROMOTE IT. By RICHARD M. SHERRY, M.D. New York: D. Appleton & Co., 1879. Pp. 185.

A GREAT deal of popular hygienic literature is being supplied us just now. The fact indicates that the public is arousing to the importance of taking care of itself, and even though this popular interest in Health Primers, Health Guides, etc., be a somewhat spasmodic one, it cannot fail to leave a permanent impression in improved habits. We can welcome the present book, therefore, as a useful contribution to the subject. It has no remarkable features, either good or bad, but the author is a candid and reliable compiler of hygienic details which will, no doubt, be of value and interest to the laity, although he presents nothing new to the physician.

PRACTICAL INSTRUCTION IN ANIMAL MAGNETISM. By J. P. F. DELEUZE. Translated by T. C. Hartshorn. Revised edition. New York: Samuel R. Wells & Co., 1879.

THIS book is addressed to the general public, and may therefore be excused for its entire lack of scientific value. As far as its matter is concerned we find it to be quite beyond criticism—in the same sense that Mother Goose is. It has stories of second sight, previsions and post-visions, mysterious fluids, complicated passes, and miraculous cures, which are full of interest and stimulus to unbalanced imaginations, but of no particular value to persons who desire well-demonstrated truths. We do not doubt, of course, the main facts concerning the peculiar nervous conditions referred to here as mesmeric and somnambule states. But the book is an illustration of how valueless the most interesting phenomena become when interpreted and distorted by the light of puerile theories.

NAVAL HYGIENE. Human Health and the Means of Preventing Disease, with Illustrative Incidents, Principally derived from Naval Experience. By JOSEPH WILSON, M.D., U.S.N. Second Edition. Philadelphia: Lindsay & Blakiston, 1879. Pp. 274.

THIS is a book which treats its subject practically and pleasantly, without being either very exhaustive or very scientific. It is, indeed, intended for naval men generally, and not for the surgeons alone. One of the more interesting among the not very abundant original notes concerns the use of farinaceous drinks. The firemen employed about the furnaces are sometimes greatly exhausted by heat, the profuse perspiration making a large quantity of water necessary to supply the waste. Cold water on an empty stomach in these circumstances might produce sudden death. By mixing three or four ounces of oatmeal, however, to the gallon of water, the danger is obviated, and the drink seems to fill the blood-vessels without increasing the cutaneous exhalation. Other illustrations of the value of such farinaceous drinks are given.

EIGHTY-NINTH ANNUAL REPORT OF THE NEW YORK DISPENSARY, January, 1879.

THIS is the oldest and one of the best conducted dispensaries in the city, and its report, which is made up with more care than such documents usually receive, shows that its work is very extensive. The resident population of the dispensary district is 180,000, of whom 38,051, or one in five, have been treated during the past year. In 1877, there were 43,623 cases relieved, showing a decrease of over five thousand in

1878. This decrease is accounted for by the fact that during the year the practice of charging a small sum for prescriptions and medicine has been introduced. This plan we believe to be a ridiculously inadequate attempt at dispensary reforms, but it seems to be thought a success by the dispensary officers, and the five thousand decrease of patients mentioned is supposed to represent, to some extent, the number of undeserving cases that would have been treated.

LECTURES ON ELECTRICITY IN ITS RELATIONS TO MEDICINE AND SURGERY. By A. D. ROCKWELL, A.M., M.D. New York: Wm. Wood & Co., 1879.

This little octavo book, of some 100 pages, is one that may be read with much satisfaction by the general practitioner. It is short, concise, and explains the practical points that one needs in electro-medicine without wasting time with theoretical considerations or going deeply into the hazy regions of electrophysics. An abundance of cuts illustrate the more common instruments that are in use. At the close of the book there are a series of pithy paragraphs, giving in plain language the practical applications of the different currents to various affections, as shown by the personal experience of the writer, and those of other competent specialists. The book will certainly serve as a useful guide for the physician or surgeon who is anxious to get a brief survey of the field of electricity from a medical standpoint, or is desirous of carrying out electrical treatment in any of the various instances in which this valuable therapeutic agent is indicated.

FASTING GIRLS: THEIR PHYSIOLOGY AND PATHOLOGY. By W. A. HAMMOND, M.D. New York: G. P. Putnam's Sons. 1879. P. 76.

This is a very interesting and readable little work, in Dr. Hammond's usual graceful style. The book is evidently written with especial reference to the somewhat celebrated Mollie Fancher case, of Brooklyn, which exercised the popular mind so strongly during the latter part of last year. In addition to two chapters upon the aforesaid Brooklyn case and upon the physiology of inanition, the remainder of the book is devoted to a consideration of some of the more remarkable cases of prolonged fasting which have been referred to by ancient and modern writers, including that of Sarah Jacob, the Welsh fasting girl, and Louise Lateau, the Belgian stigmatisee. While not going exhaustively into the subject, Dr. Hammond presents a very strong case, and fully accomplishes the object expressed in the preface, of doing something "towards the removal of a lamentable degree of popular ignorance." The book will be read with satisfaction by medical men as well as laymen.

AN ATLAS OF HUMAN ANATOMY, Illustrating most of the Ordinary Dissections, and many not usually Practised by the Student; accompanied by An Explanatory Text. By RICKMAN JOHN GODLEE, M.S., F.R.C.S., of University College. Philadelphia: Lindsay & Blakiston. 1878. Part I.

This work is in large folio, and contains four colored plates with two figures on each plate. They illustrate the anatomy of the neck, and both drawing and coloring are extremely well done. The object of this Atlas, as stated by the author, is to supply a full illustration of the anatomy of the human body in a convenient form; to present dissections not ordinarily undertaken, as well as to give a better idea of the relations of parts; and to make the dissections follow each other in such a way that the student may work out more easily the steps by which particular organs and regions are to be exposed.

The work is very finely executed, and is one that will be of great help in dissection and in accompanying anatomical studies.

PROCEEDINGS OF THE EIGHTY-NINTH ANNUAL SESSION OF THE MEDICAL SOCIETY OF DELAWARE. At Lewes, Del., June, 1878.

This pamphlet contains the able opening address of the President, Dr. William T. Collins, and an extremely curious case of pelvic cellulitis, reported by Dr. W. T. Skinner. Mrs. T., aged 65, was attacked, without known cause, with pelvic cellulitis. It resulted in suppuration and the establishment of an undoubted *utero-intestinal fistula*, pus and faeces being freely discharged through the os and vagina. The fistula was connected with the small intestine. The patient slowly recovered. This is, we believe, the fifth case of the kind ever reported. Dr. H. Burton was elected President, and Dr. Geo. Troup Maxwell, Secretary, for the ensuing year.

TRANSACTIONS OF THE AMERICAN DERMATOLOGICAL ASSOCIATION. Second Meeting, at Saratoga, August, 1878. Reported by the Secretary, Dr. R. W. Taylor, New York: D. Appleton & Co. 1879.

The papers read at this meeting are noticeable for their treating especially of the rarer skin affections, and the general practitioner is likely to be somewhat dismayed at the long contributions and exhaustive discussions upon Xeroderma, Ulceration, Scrofuloderma, Inflammatory Fungoid Neoplasm, The Trichophyton Tonsurans, etc. They indicate enthusiastic and careful study in this department of medical science. The more practical articles upon the Use of Linseed Oil in Skin Affections, and The Treatment of Hirsuties have appeared more or less fully in the RECORD. A classification of skin diseases was adopted by the Association. Statistics concerning the prevalence of leprosy in America are given. These show its presence, to some extent, in the Gulf States, in Minnesota, and amongst the Chinese in California.

THE DISEASES OF LIVE STOCK AND THEIR MOST EFFICIENT REMEDIES; INCLUDING HORSES, CATTLE, SHEEP, AND SWINE. By LLOYD V. TELLOR, M.D. Philadelphia: Dr. G. Brinton, 115 South Seventh Street. 1879.

This work is a compilation, by a practising physician, not a veterinary surgeon, of an immense amount of valuable information taken from the works of such veterinary authorities as Professor William Williams, Finlay Dun, John Gamgee, George Armitage in Great Britain, and Law, Townshend, Chawner, etc., in our own country. It is not strictly for professional men; indeed, it is hardly comprehensive enough for a veterinarian, as it contains no reference to pathology. For farmers, country gentlemen, and dealers, it would seem to be a plain, practical book. It is evidently written by an accomplished physician, who merely exposes what is really known, and omits all that is doubtful or theoretical. The therapeutical portions are clear, precise, and simple. For physicians in country practice, who are at all times likely to be called on to become veterinarians, it will furnish an excellent resource in cases of emergency. It is well classified, and has a good index.

COD-LIVER OIL EMULSION.—℞. Calcis et sodæ hypophosphit., ʒij; Ext. malti, fʒij; Ol. morrhue, fʒiv; Aquæ, fʒij; Ol. amygd. amar., ℥. iv. M. Sig.—Tablespoonful an average dose.—Dr. M. L. JAMES in *Trans. Med. Soc. Va.*, 1878.

Reports of Societies.

OHIO STATE MEDICAL SOCIETY.

THIRTY-FOURTH ANNUAL MEETING, HELD AT DAYTON, O., JUNE 3, 4, and 5, 1879.

(Special Report for THE MEDICAL RECORD.)

THE Thirty-fourth Annual Meeting of the Ohio State Medical Society took place at Dayton, O., June 3d, 4th, and 5th. The meeting was a large and enthusiastic one.

Papers were presented as follows:

ADDRESS OF WELCOME, by Dr. J. M. Weaver, of National Soldiers' Home.

The Treatment of the Various Forms of Consumption. By Dr. Roberts Bartholow, of Cincinnati.

The Preservation of Good Eyesight and the Use of Spectacles. By Dr. J. H. Buckner, of Cincinnati.

Hog Cholera. By D. N. Kinsman, Columbus.

Report on Progress of Surgery. By Dr. S. F. Forbes, of Toledo.

Mixed Anæsthesia. By Dr. J. C. Reeve, of Dayton.

Report on Progress of Gynecology. By Dr. Thad. A. Reamy, of Cincinnati.

National Sanitary Science. By Dr. G. E. Walton, of Cincinnati.

Glaucoma. By Dr. S. C. Ayres, of Cincinnati.

Plaster-of-Paris Roller in Treatment of Club-foot. By Dr. P. S. Conner, of Cincinnati.

Tubercle. By Dr. H. J. Herrick, of Cleveland.

Medical Mispronunciation. By Dr. A. C. McLaughlin, of Tremont City.

PRESIDENT'S ADDRESS. By Dr. B. B. Leonard, of West Liberty.

CONSOLIDATION OF MEDICAL COLLEGES.

The Committee appointed last year on the Consolidation of Medical Colleges, where two or more exist in one city, reported that they had had a meeting, but that no union was feasible, and asked to be discharged.

DUTY ON QUININE.

A motion that Congress be requested to abolish the duty on quinine was carried unanimously.

Fifty-four new members were added.

THE METRIC SYSTEM.

A large number of tracts from the Boston Metric Bureau were received and distributed. Near the close of the Session, and at a time when the attendance was unusually full, a motion was made to adopt the metric system, in papers presented, transactions, etc. After a speech by Dr. J. F. Baldwin, of Columbus, made neither for nor against the system, but simply that the members might vote intelligently on the subject, followed by remarks by Drs. E. H. Hyatt, of Delaware, and H. J. Herrick, of Cleveland, the resolution to adopt was unanimously voted down; *unanimously*, not because no body voted for it, but because every body voted *against* it. Dr. Baldwin was also, by vote, requested to embody his remarks in a paper to be published in the Transactions, and also to be sent for publication to the medical journals.

OFFICERS ELECTED FOR THE ENSUING YEAR:

For President—J. A. Murphy, M.D., of Cincinnati.

For Vice-Presidents—John Davis, M.D., of Dayton; Thos. G. McBright, M.D., of Akron; J. D. Edwards, M.D., of Xenia; C. A. Kirkley, M.D., of Toledo.

For Treasurer and Librarian—T. W. Jones, M.D., of Columbus.

For Secretary—J. F. Baldwin, M.D., of Columbus.

For Assistant Secretary—Jesse Snodgrass, M.D., of Kenton.

The next Annual Meeting will be held at Cleveland, commencing June 15, 1880.

ARKANSAS STATE MEDICAL SOCIETY.

YELLOW FEVER AND QUARANTINE.

REPORT BY DR. R. G. JENNINGS.

Special Report for the MEDICAL RECORD.

AT the annual meeting of the Arkansas State Medical Society, held in Little Rock, May 14 and 15, 1879, Dr. R. G. Jennings made a report, of which the following is an abstract of his statements with reference to yellow fever and quarantine.

When it was reported that yellow fever was spreading rapidly at New Orleans, the Little Rock city council appointed (August 3d) a board of health. That board met and organized August 6th, and at once declared a quarantine against New Orleans. August 13th, reports from Memphis announced one case of yellow fever, and the next day two deaths and nine new cases. Quarantine was declared that day, August 14th, against the city of Memphis and all other infected places in the Mississippi Valley. The freight and passenger trains on the Memphis and Little Rock Railroad were stopped running altogether.

Arkansas not having established a State board of health, all expectations of beneficial results from a quarantine centred in the city of Little Rock; and to the action of its board of health the attention of the whole people of the State was directed. After the quarantine at Little Rock was in full force and effect, a large number of incorporated towns along the public highway of travel followed her example, and established independent local quarantines, adopting such sanitary measures as were deemed essential, and imposing such restrictions as were considered expedient. Notwithstanding all those precautions taken, and a rigid enforcement of such regulation, undoubtedly cases of yellow fever or some other disease of a very close kinship did enter the State. At Augusta, Woodruff County, some half dozen or more suspicious cases occurred, that proved fatal. Those cases were supposed to be yellow fever. Fortunately the disease neither became general nor spread into the country, and entirely disappeared with the first frost. Quite a number of cases of yellow fever occurred at Hopefield, opposite Memphis. The disease first appeared among refugees from that city, and soon attacked a majority of the people of Hopefield. It only ceased for want of material, though it continued until the appearance of frost. A young lady went from Memphis to Helena, had the yellow fever, and died with it there. One case afterwards was reported as having recovered from it. Then all reports of the disease from that place ceased for some weeks, when either the revival of the fever occurred, or other disease equally as fatal sprang into existence, and threatened the city. When the reports of new cases had reached the large number of sixty in one day, frost occurred, and there were no more published reports from Helena. There seemed

to have been a diversity of opinion among the Helena physicians as to the true character of the latter outbreak; but its reported rapid extension and great fatality lead to only one solution of the problem, which could be best stated by asking: If it was not yellow fever, what was it? One case of yellow fever occurred at Washington, Hempstead County, in the person of Rev. Richard Samuels (colored), who died on the eleventh day of the attack from relapse. That case created considerable alarm among the people. The Washington Board of Health, however, acted promptly, established a *shotgun* quarantine around his house, which fortunately was isolated, something over a mile from the town, preventing all ingress and egress except upon necessity, and after his death destroyed everything liable to become infected, and thus prevented any spreading of the disease. The case of Samuels presented something of a connective history, and he could not refrain from giving it, for a twofold purpose, viz., that it was connected with another case, to be reported, and it illustrated the manner in which infection might be transported for long distances, both of which would be found of much interest. Four colored ministers—three from the southern portion of the State, and one from Little Rock—passed through Memphis, August 3d, to attend a religious convention at Jackson, Tennessee. They remained at the latter place some ten days or two weeks, where they obtained health certificates. When they arrived at Humboldt, they had to wait the greater portion of the night for a train. Seeing a box freight-car open, half full of rice in sacks, direct from New Orleans, they concluded to enter the car and sleep awhile. Two of them lay down upon the rice-sacks, and the other two upon the floor of the car. All four returned to Little Rock, where they remained one day, when three of them continued their journey to their homes in the southern portion of the State. Samuels, one of the two who had slept upon the rice-sacks, had but reached home before he was taken down with yellow fever and died, as previously reported. The Rev. Jas. Reed (colored), one of the four ministers, and one of the two who slept upon the rice-sacks, returned to Little Rock, his home, with the others. As soon as it became known Samuels had the fever, Dr. Jennings sent the chief of police after Reed, knowing he was with him. Reed could not be found, and the chief of police reported that his house was closed. Thus the matter rested. Some weeks after this, Reed's wife returned to the city, but not until all danger of the communication of the disease was over, and reported that Reed, believing he would have the yellow fever, and knowing the excitement in the city among the people about it, took his little family and removed beyond the Fourche Mountain, a distance of over three miles from the city, into an isolated cabin, where he had the fever, and died with it. It was a little singular that only the two who slept upon the rice-sacks had the fever, more particularly so as they all had considerable discussion upon the subject prior to lying down—the two who slept upon the floor of the car contending that it would be dangerous to sleep upon the sacks, and the two who slept upon them taking the opposite ground, believing there was no danger. Those facts were given by Samuels prior to his death, and corroborated by the two men living. Thus Little Rock, after all the rigid enforcement of her quarantine, came very near having a case of yellow fever; but the circumstance of Reed's death was known by only a few persons, and had never been made public until the present. Fortunately the disease was never communicated to any other person.

NATIONAL BOARD OF HEALTH.

Adjourned Meeting, held at Atlanta, Ga., May 5, 1879.

JAMES L. CABELL, M.D., LL.D., OF VIRGINIA, PRESIDENT, IN THE CHAIR.

MARITIME QUARANTINE—QUARANTINE REGULATIONS FOR SAILING-VESSELS.

DR. JOHN S. BILLINGS, U.S.A., Washington, D. C., reported that the order of business for the day was the exclusive discussion of the question of maritime quarantine under the following heads:

1. The sanitary history of a vessel in a foreign port; embracing the means of securing the best possible sanitary condition of the cargo, passengers, and ship destined for the United States.

2. The sanitary regulation of vessels during the passage.

3. The methods and regulations for preliminary inspection and quarantine upon the arrival of the vessel.

4. The treatment of the passengers and care of the men upon the ship.

5. The treatment of the cargo and ballast.

6. The treatment of the ship after disposition of the passengers, and the regulations necessary to secure its thorough sanitary condition.

The President called upon Dr. S. O. Vander Poel, Health Officer of the Port of New York, to open the discussion.

DR. VANDER POEL remarked that formerly he thought it impossible to establish in this country a system of national quarantine, so varied were the interests and the climate of the various localities exposed to invasion from foreign ports. He had, however, reached the conclusion that a national system of quarantine could be established upon one principle, namely, that it should confine itself to the sanitary regulation of the different ports, and leave the ports to perfect its own police regulations.

The term quarantine he regarded as an unfortunate one, because there was associated with it the idea of detention. *Detention* really had nothing whatever to do with thorough quarantine, and the idea should be entirely removed. To prepare the way to the discussion of the several topics submitted, he offered the following general propositions:

1. That quarantine did not recognize detention as a necessary factor, except so far as it pertained either to the invasive processes of disease or to the time requisite to secure the proper sanitary condition of passengers, cargo, and vessel.

2. The manner of transmission of disease and the incubative period must be made the basis of action.

SAILING-VESSELS.

No objections or comments being offered to the general propositions,

DR. VANDER POEL remarked upon the *first* question, namely, measures necessary to secure the best possible sanitary condition of a vessel while in a foreign port, that the following were requisite:

1. Daily pumping out the bilge-water until it came out clean.

2. Careful regulation of the diet of the crew, and seeing that they returned to the vessel at a specified time.

3. Daily bathing and change of clothing.

4. Daily movement from the bowels.

While the vessel was in transit, all those precautions should be taken as fully as possible. Absolute clean-

liness of the ship was the great essential, but especially of the bilge.

The President then called upon representatives from the different ports along the Atlantic coast, and responses were made by Dr. Cleeman, of Philadelphia; Dr. Howard, of Baltimore; Dr. Nash, of Norfolk; and Mayor Cobb, of Pensacola. Those gentlemen endorsed the propositions in the main, both general and special, given by Dr. Vander Poel.

Dr. Howard thought it extremely questionable that the germs of yellow fever always sought the bilge, as suggested by Dr. Vander Poel, and believed that they were more likely to be found in the dirty clothing and quarters of the sailors.

The next topic—*The methods and regulations for preliminary inspection and quarantine upon the arrival of the vessel*—being open for discussion, Dr. Vander Poel remarked that he detained the vessel not less than forty-eight hours, because a certain length of time was required to secure thorough cleanliness, and use some simple disinfectant. He usually employed chlorine, as it was more simple and equally effective as sulphur. After that the hatches were opened, and fumigation made in every tenable part of the vessel. The vessel was fumigated twice daily during the entire time it remained at Quarantine. When that was done, the vessel was discharged; and it was discharged at the earliest possible moment, for the simple reason that, after it was fumigated, the longer the cargo remained the more violent would be the disease. The cargo should be discharged as soon as possible, fumigation practised at the close of each day's work, and usually at the end of two days the ship was entirely lightered. The lighters were not allowed to return to the city during the quarantine season. If, in exceptional instances, return became necessary, the men must remain without exposure until the period of incubation—five days—had passed. Any man who worked in the hold of the vessel during the discharge of the cargo must remain five days after the vessel was emptied, and the process of cleansing begun; and for purposes of cleansing, a scrub-broom and plenty of water was better than fumigation.

Dr. CLEEMAN, of Philadelphia, remarked that he should be afraid to endorse the system of allowing goods to be removed so early from an infected vessel.

Dr. HOWARD, of Baltimore, stated vessels were only rarely lightered at that port. Every vessel liable to be infected with yellow fever was ordered to cast anchor and remain; and when it was thoroughly fumigated and cleansed, and the clothing of the sailors was thoroughly cleansed, it was allowed to proceed directly to the docks. He regarded absolute cleanliness as more valuable than either fumigation or disinfection, so-called, although sulphur and chlorine were sometimes used. Nothing was done with the vessel after the cargo was removed.

Dr. VANDER POEL remarked that lightering did not delay the vessel; and he thought that, in New York, it would not be safe to allow the suspected vessel to go to the docks without having first discharged her cargo and been made absolutely and thoroughly clean. No case of yellow fever had been traced to the cargo in the port of New York, and no lighter had become sick by reason of special exposure during his work.

Dr. Howard agreed that lightering would be safer, but the increase in expense would be considerable. Again, if the germs were not in the cargo, why lighter? There was no advantage in it, unless it was to get at certain parts of the vessel in which he thought the germs would not be found.

AFTERNOON SESSION.

QUARANTINE REGULATIONS FOR STEAMERS.

Dr. VANDER POEL stated that steamers were less liable to become infected by yellow fever, etc., than sailing-vessels:

First. Because they were rarely in an infected port more than one or two days; they expedited all their operations, and pursued their course to a very large extent according to fixed and recognized regulations.

Second. There was much better discipline upon steamers than upon sailing-vessels. There were several recognized departments, each of which had its distinct head, and the consequence was a much better sanitary control of the whole ship than could obtain in sailing-vessels.

Third. Steamers had better appliances for maintaining proper ventilation.

Fourth. Steamers had the facilities for pumping out the bilge without difficulty. At the port of New York, steamers from Havana or other infected port were compelled to remain at Quarantine a little more than five days from the time of leaving Havana—the usual period of incubation for yellow fever. Then, if the passengers were all well, and there had been no sickness on board during the trip, they were carried to the city. Immediately after the discharge of the passengers the vessel was taken to Quarantine, the cargo discharged, and then treated the same as a sailing-vessel.

THE TREATMENT OF THE PASSENGERS AND CARE OF THE MEN UPON THE SHIP.

Upon the above topic Dr. Vander Poel remarked that all the clothing upon a sick man, before arrival, was taken from him and destroyed, and new clothing given him. He was then carried to the hospital, where his clothing was again changed, so that no clothing which came from the infected vessel ever entered the ward. The sick were supplied with what was called transfer clothing, which, on arrival at the hospital, was thrown into a disinfecting solution. The point in that minute care was to secure absolute immunity among the attendants and persons upon the island at Lower Quarantine from the yellow fever. The complete escape thus far, Dr. Vander Poel ascribed to the care taken to prevent the admission to the wards of the hospital of any clothing taken from the infected vessel.

Dr. HOWARD, of Baltimore, agreed with Dr. Vander Poel with reference to the comparative liability of steamers and sailing-vessels becoming infected with yellow fever, and carrying it from one port to another. With reference to the sick on board, he took them ashore without changing the clothing, placed them in wooden barracks, and allowed them to wear the same clothing, which was at once destroyed as soon as either death or recovery took place. They had not had a case of yellow fever originating in the hospital. Post-mortems had been made in nearly all the fatal cases, and no physician had taken the disease; and he attributed the exemption of the attendants and the physicians to the fact that all clothing, bed and bedding, and other porous articles used about the patient, were immediately destroyed as soon as either death or recovery occurred.

Dr. VANDER POEL remarked that if the effluvium of the disease was transmitted by clothing, it was a proper precaution to take special care of the clothing before the patient was allowed to enter the wards of the hospital.

Dr. FOLSOM, of the port of Boston, remarked that

their procedure was very nearly the same as that in operation at the port of New York. In certain cases vessels coming from a port at which yellow fever was prevailing were not allowed to reach the city during the hot weather, but were detained at Quarantine until the cold season arrived, unless special precautions were instituted by the owners of the vessel and the cargo.

DR. NASH, of Norfolk, remarked that his experience was very much like that related by Dr. Vander Poel with regard to steamers and sailing vessels.

DR. CLEEMAN, of Philadelphia, remarked that he had nothing to add to what had already been stated with reference to sailing-vessels and steamers. The sick with yellow fever were removed to the hospital generally, and the clothing was usually destroyed, sometimes only disinfected. He gave a brief account of cases which originated in Philadelphia from handling cargoes.

MAYOR COBB referred to the spread of yellow fever from dismantling a ship in the port of Pensacola.

DR. WHITE, of New Orleans, was inclined to agree with Dr. Vander Poel with reference to steamers and sailing-vessels. He regarded the suggestions with regard to the care of the clothing and the bedding, as very proper. He also concurred in the ideas advanced with reference to the treatment of the vessels and the men while in foreign ports and in transit.

DR. DOWELL, of Galveston, Texas, remarked that the vessels which had sickness on board on arriving at that port were retained, but they had no means for unloading ships or disinfecting cargoes.

The discussion then gave way to the reading of a paper by Dr. CHANCELLOR, of Baltimore, Md.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Adjourned Meeting, April 21, 1879.

DR. A. E. M. PURDY, VICE-PRESIDENT, IN THE CHAIR.

THE RESPONSIBILITY OF THE MEDICAL PROFESSION FOR THE ABUSES OF MEDICAL CHARITIES.

The special order for the evening being the above subject, DR. F. R. STURGIS gave a brief *résumé* of the discussion upon the same question at an adjourned meeting, held April 14, 1879. The discussion was continued by DR. D. B. ST. JOHN ROOSA, who considered two points in the paper presented by Dr. Sturgis. 1. The author of the paper had expressed the opinion that the medical profession was to blame for the present abuse of medical charity, and that there were a great many in the city who could pay a moderate fee for medical services, but who were receiving such service at dispensaries and hospitals without fee or reward to the attending physician. Dr. Roosa thought it was admitted that the evil existed not only in our dispensaries, but also in our large hospitals. Indeed, it had become a feature of some of those hospitals, built with funds which were acquired from the public under the notion that they were charitable institutions, to put apart rooms, that were fitted up sufficiently well to satisfy the wealthiest people in the land, and into which they could admit patients who paid well for their board and medicine; whereas, the medical adviser, in many instances, received nothing whatever for his services. He regarded that kind of management as a fraud upon the dead men and women who gave money to found a charity. The hospital that provided for the well-to-do, without paying the med-

ical adviser, was no longer a hospital in the sense in which that word was understood in this country; it was a boarding-house for the benefit of people who wished to shirk their doctor's bills; and if doctors connived at that kind of charity, they did themselves harm, and their brethren much more harm. The author of the paper was correct in his estimate of the place where the blame should rest; and if the abuse of medical charity was an evil for which the medical profession was to blame, who was to remedy it? Certainly the medical profession itself. Suppose the medical profession of the city of New York should say that, from that time henceforth, as a matter of duty, they would no longer treat a single individual, either in dispensary or hospital, without fee who was able to pay a fee, how long would it be before the abuse would be broken up? The remedy was in the hands of the profession, were we united; but if discordant, we might go on for the next fifty years aiding and abetting the system of treating, in supposed charitable institutions, people who were able to pay for medical services. 2. There was a necessity for unanimity of action. When, two or three years ago, the great eruption in the profession took place regarding the management of a certain hospital in the city of New York, it seemed that almost every member of the profession was upon one side, yet the careful observer could see that the names of certain prominent medical men—men of influence and deserved position—were not with the majority; and one of the astute lawyers, who was upon the Board of Direction of that institution, remarked at that time, "It is not so important as to whose names you have, as to whose you have not." But, as a matter of history, five or six eminent men in the profession, who were at variance with the large majority of their brethren, were able to thwart and practically defeat the effort which, in the opinion of the majority, would have put us twenty-five years further onward in our struggle with Boards of Direction. What did that teach with reference to the present agitation? It taught that we might go to the County Medical Society, secure the presence of gentlemen eminent in the profession, get a vote of 450 to 50 in favor of plans which the majority might advocate, and yet, unless the leaders in the medical profession were united, it would come to naught, and we should simply be where we started, with one *important exception*. The exception was that, although we might fail in the undertaking at the time, we were steadily creating a healthy public sentiment. If we were right in the matter, the agitation would bring about the day when the medical profession would refuse to be dictated to upon subjects which pertained to its own welfare, and upon subjects of which it was fully capable to judge, and we should reach the time when we could demand our common rights. We might not be able at once to eliminate the would-be paupers, who were clothed in purple and fine linen and fared sumptuously every day, but the time would come when only paupers would be treated in dispensaries, and only paupers would be lodged in hospitals.

DR. WILLARD PARKER gave a somewhat detailed account of what he had seen of hospitals, dispensaries, etc., since the year 1839, when he first came to the city of New York. At that time no trouble of the present kind existed, and the city contained about 312,000 inhabitants. There was one hospital, the New York Hospital; three dispensaries, the Old New York, the Northern, and the Eastern; one Eye Infirmary, and one Insane Asylum. Those institutions—some of them eleemosynary, and some otherwise in

character—seemed to meet the demand. At that time we had but few tenement-houses, and those were held by substantial men, who built them for the accommodation of a few families. In 1845, '46, and '47, came the marvellous immigration to this country from Ireland, and within the space of one decade, from 1840 to 1850, the population of the city increased between two and three hundred thousand. Our population had been steadily increasing from that time until our numbers were now so great that in some parts of the city there were only nine square feet for each person. When the immense immigration to New York took place, the good people of the city were moved by sympathy, and at once commenced to provide for the necessities of the immigrant, and that sympathy led to the establishment of various eleemosynary institutions to meet the demands which charity imposed upon the city. The first new hospital was built about the year 1850, and since that time we had gone on until it was perfectly marvellous how many hospitals, dispensaries, and charitable institutions at present existed among us. We had an immense population, and the charity had grown into almost, in many instances, a curse. There were many people who felt that when they had contributed their money their responsibility was at an end, but it should be recollected that we were only trustees of our money, should be careful that it was placed where it would do good, and not harm, and were responsible for the transaction. Doubtless, there was too much charity bestowed in the city.

There were three kinds of persons who employed a doctor: 1. Those who had means, so that they could pay a physician a small fee; that class was small in comparison to what it was forty years ago. 2. Those who were honestly poor, "God's poor," and for that class he had great respect. 3. Those who were sometimes called the "devil's poor," and of that class there was a large number. The question arose, what could we, as professional men and as *citizens*, do under the circumstances, surrounded as we were by charitable people, charitable institutions, and a large population which were here merely to be supported? Dr. Parker did not see how any relief could be obtained by legislation, nor did he see how either the State Medical Society or the County Medical Society could bring about the desired correction of abuses. The only way of escape which opened up before him was, that *we should help ourselves*. How was that to be done? After discussing at some length the relation existing between the doctor, the taxpayer, and the beneficiary, he remarked that he believed the first thing to be done was for the profession to take care of itself, and let every man stand upon his own foundation. He believed that every man should have his own dispensary. It must be an individual and collective taking care of ourselves. Let every man have his own dispensary, dispense his own medicines, and do his own work. If a committee from the Society could meet the Board of Directors of dispensaries, perhaps some plan might be reached by which these institutions could unitedly be induced to adopt the remuneration system, which met his hearty approval. The plan adopted at the New York Hospital might yet turn out to be a blessing to us, if we looked at it properly.

Dr. HENRY remarked that there never was an evil in the world for which there was not a remedy. He was surprised that Dr. Parker advocated that every man should have his own dispensary and dispense his own medicines, for it was a violation of the constitution and by-laws of the Society. The remedy proposed by

Dr. Henry was to cut off the supply of doctors by cutting off the supply given to the medical profession for the medical schools. Open the hospitals to competitive examination, and also the dispensaries, and when a vacancy occurred let the position be filled by competitive examination. If the supplies for the medical colleges could be cut off, it would enable the men who were in the profession to live.

Dr. PARKER remarked that he did not wish to be understood as favoring the plan of several gentlemen uniting and establishing a dispensary, as suggested in the paper; but rather that every man should do his work in his own dispensary, which was virtually doing his work in his own office at certain hours.

Dr. JACOB thought that if there was a less number of doctors perhaps we should not have so much reason to complain; that if greater care was taken in recommending applicants for positions as dispensary physicians, a better class of men could be obtained; and that there would be less abuse of the position for the purpose of establishing a private practice over the backs of the poor. The abuse which a large number of doctors connected with dispensaries and college clinics practised, for the purpose of obtaining patients who were able to pay, was well known; and perhaps it had not been spoken of at all. The very fact that there were a large number of men who wished to build up a private practice out of a dispensary practice, was a reason why so many would crowd into dispensaries as physicians who were not qualified to be there. What could be done to correct the abuse? Care on the part of those who were solicited to sign applications for positions as dispensary physicians, and a few plain questions, would rid the ranks of many unworthy applicants. In the German Dispensary, which was about twenty years old, it was a rule rigidly enforced, that every doctor should question every doubtful patient, and in that manner a large proportion of people had been crowded out; and the fact was, that out of a great many thousand applicants for medical advice there were but relatively few who did not deserve the charity. Again, in the college clinics, many applied who were able to pay fees; and he had made it a rule in his own clinic not to prescribe for any such person. One person sent off in that manner, in the hearing of those who had a right to be there, would frighten twenty who were not entitled to the benefit of charity, and they would either leave or not come. Much of the abuse could be corrected if the doctors in those places and institutions would be thoroughly in earnest in the matter.

Dr. JACOBI believed that the proposition to establish dispensaries under the control of any given number of doctors—not a free dispensary, but a paying one, as suggested by Dr. Sturgis—was more dangerous and demoralizing than anything which he had heard against dispensaries. The New York Hospital plan, which allowed any one to go there for *one* dollar a month, was not much worse. All had been opposed to the New York Hospital plan, because *one* dollar a month had been set down as the value of professional services. It was demoralizing to the public; and if there was anything nearly so bad as that plan, it was the plan suggested by Dr. Sturgis. Dr. Sturgis meant to work for *ten* cents a month. Such a plan would be adopted for the purpose of making money; and the dispensary proclaimed that, for five, ten, or fifteen cents, or whatever the amount might be, the best of medical service could be obtained. The public would say at once, "If medical service is worth only *ten* cents, I am not a pauper, and I will pay the doctor what he charges, and I have a

perfect right there." It was the *vast minority* to which Dr. Sturgis referred, that we wished to benefit; but we could not do so by placing any charge upon medical services in a charitable institution. He had frequently thought that it would be better to wipe out the dispensaries entirely, when he looked at the abuse of the charity sustained by both the medical profession and the public.

DR. BEVERLEY ROBINSON, for the purpose of correcting some "erroneous statements" which had been made regarding the medical service at the New York Hospital Dispensary, read the following, which could be seen in conspicuous places in that institution: "This branch of the service of the hospital is designed as an efficient means of extending medical and surgical treatment, mainly to the industrial classes. To prevent abuse of the service, physicians will not be expected to treat such patients as have the means to avail themselves of medical service outside."

DR. PARSONS referred to the general use made of the position as a dispensary physician to build up a private practice, and thought it unwise and unjust that the patronage should be distributed as it was. Only the strictly competent and deserving should be appointed to those places. Again, the provident dispensaries were the most improvident, for the reason that, no matter how small the fee might be, the moment a charge was made the physician's services were placed at the mercy of those who gave him patronage. The man who, under such circumstances, prescribed or performed operations, was injuring his professional brethren, because he assisted in cutting off even a moderately fair chance for others to gain experience.

RESOLUTION.

DR. ROOSA offered the following resolution:

Resolved, That it is the sense of this meeting, that the attending physicians and surgeons of the various dispensaries and hospitals should diligently inquire with regard to the financial circumstances of all patients in those institutions, and should refuse to treat those whom they believe to be able to pay small fees."

DR. HENRY indorsed the resolution.

DR. E. S. BATES sustained the resolution. He believed that it was one step in the right direction, and perhaps others would follow.

DR. MESSINGER thought that, if the people were made to take care of themselves, there would be found but comparatively few in this city who were really paupers. He also believed no man should be appointed as dispensary or hospital physician or surgeon who had not proved himself to be the best man for the place. He favored the resolution.

DR. PARKER asked, "How shall the resolution be put into operation?"

DR. ROOSA replied, his idea was that the County Medical Society represented the sense of the profession, and that every loyal member of the profession would respect an expression of that sense. If, therefore, the County Medical Society passed unanimously such a resolution, he thought something would be done towards correcting what by all was acknowledged to be a great abuse and evil. If every dispensary, hospital, and college physician would inquire diligently with regard to every dispensary, hospital, and college patient, and *not* prescribe for those who were able to pay, much could be accomplished towards bringing about the desired reform.

DR. PARKER remarked, that his suggestion would be to appoint a committee from the Society to confer with the Boards of Trustees of dispensaries, with reference to the subject under consideration, and to report to the Society.

DR. ROOSA remarked that he had no objection to Dr. Parker's suggestion as a secondary topic; but let us first say, with an uncertain sound, that we had a right, in spite of all Boards of Trustees, to say that we would not, either in hospitals, or dispensaries, or colleges, or infirmaries, treat patients gratuitously who were able to pay for medical service.

DR. ROOSA'S resolution was unanimously adopted, and the Society adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, April 23, 1879.

DR. E. L. KEYES, PRESIDENT, IN THE CHAIR.

REPORT OF MICROSCOPICAL COMMITTEE.

DR. W. M. CARPENTER submitted the following report from the Microscopical Committee:

The result of the examination of the specimen presented by Dr. J. W. Howe, at the Stated Meeting, held April 9, 1879, is as follows:

FIBROMA UNDERGOING BONY AND CAVERNOUS CHANGE.

Cuts were made through the substance of the growth in various directions, the results showing that it was surrounded by and made up, to a large extent, of connective tissue, in which were numerous deposits of bone in the form of spiculæ, nodules, and irregular masses. In some portions there were large collections of blood in spaces, resembling those of erectile tissue.

Microscopic examination corroborated the naked-eye appearances. The blood was mostly contained in dilated vessels with extremely thin walls, often closely applied to one another. At some points there was a large collection of lymphoid elements, such as are often noticed in the vacuity of blood-vessels, especially when they have been distended with blood. In most places the fibrous tissue was of the fibrillated variety, and showed no indications of active change. There was no striped or unstriped muscular tissue, and no cartilage. The muscular tissue, which is sometimes found in such growths, had possibly been replaced by the fibrous elements during the slow growth of the tumor. Commencing originally as a fibrous deposit in the inter-muscular planes, it may have undergone a partial change into bone and cavernous tissue. Either of these phenomena has been observed before, but their joint occurrence seems to make the growth unique.

T. E. SATTERTHWAIT.

As a supplement to the above report, the following is submitted: One of the constituents of all sarcomatous growths is blood-vessels. These are sometimes found so abundant as to give rise to a condition that has received the special name sarcoma teleangiectodes and, when present in large numbers, there is great liability to hemorrhages. In the specimen presented blood-vessels were very abundant.

Sarcomata occur between the muscles, on fasciæ, and have their starting-point in the periosteum; and osteoid sarcomata are quite uniformly connected with bones. They are occasionally multiple throughout their course, but generally are single. In the present specimen the growth was connected with the periosteum, but it was difficult to ascertain whether

or not it began as two distinct nodules. It was intimately connected with fascia, and contained unmistakable bone corpuscles.

There is a form of the disease which has been described as *diffuse sarcoma*, and which is seen especially among "the muscles in the female breast and in the testicles." In this form the new-growth takes place in the interstitial connective tissue and at the expense of the muscular fibres, and looks like an infiltration or hypertrophy.

In the specimen presented there was a rather diffuse growth, and in all the sections examined there was a notable absence of muscular fibres.

While the cells have the appearance of fibrous-tissue cells, there is room for the opinion that some of them at least are of a sarcomatous variety, and therefore favor the impression that the tumor is sarcomatous in nature and belongs to the class which contains more than the usual number of blood-vessels.

W. M. CARPENTER.

SCIRRHUS CARCINOMA.

The result of the examination of the tumor presented by Dr. A. C. Post, at the same Stated Meeting, is as follows: The growth is made up of an abundant stroma of connective tissue, in which is a network of channels of varying size and irregularly pouched. They contain epithelial elements closely packed together. The channels give precisely the appearance of dilated lymphatics, having the same peculiar pouching which is seen in them. The name scirrhous carcinoma is therefore applicable.

T. E. SATTERTHWAITE,
W. M. CARPENTER.

MULTIPLE EXOSTOSIS.

DR. V. P. GIBNEY presented a patient who illustrated multiple exostosis. The boy, *æt.* 16 years, was exhibited to the Society in 1875, and at that time the interest in his case centred on the existence of an exostosis about the left hip-joint, and giving rise to symptoms of disease of that articulation. During the last four years he had had only one week of pain, which was mild in character. At the present time the bony tumors were increasing in size. They existed symmetrically near the proximal ends of the humerus, the distal ends of the radii, and the heads of the tibia, and varied in size from that of a peanut to that of a walnut. There was one on the first phalanx of the index-finger and above the left trochanter major. The joints remained intact, and it was thought that at the age of the patient no great increase could take place.

CANCEROUS STRICTURE OF THE ŒSOPHAGUS.

DR. LOUIS ELSBERG presented a specimen of cancer of the œsophagus. Two months previously, the patient came under his observation, when there was a slight contraction of the tube at the level of the cricoid cartilage. Below that point was a stricture that only admitted a sound one-fourth of an inch in diameter. Death occurred from exhaustion, and at autopsy a cancerous mass was found attached to the vertebral column. An opening from the œsophagus to the trachea existed. The debility of the patient contradicted the operation of gastrotomy.

MORBUS CRANII — EXCISION OF HIP-JOINT UNDER LISTER.

DR. JOSEPH W. HOWE presented specimens accompanied by the following histories: Joseph Lennis, *æt.* 19, occupation printer, was admitted to St. Francis' Hospital, March 31st. Three years ago the patient

fell down a flight of stairs and struck on his right hip. There was a slight swelling and some pain over the part for a few days afterwards. It gave him very little inconvenience, and he continued at work as if nothing had happened. Twelve months subsequently he began to have some pain and stiffness in the joint, which made him limp. Those symptoms increased in severity to such an extent that he was finally compelled to take to his bed, where he remained under treatment for three months. He was then allowed to go about, and was able to walk without much pain. For a period of five months he suffered but little, but did not put the lame foot to the ground. An abscess formed, which opened on the outside of the joint and had continued to discharge ever since.

On examination, the limb on the affected side was found to be shortened to the extent of nearly two inches. The foot was inverted, and the limb adducted. Considerable pain existed whenever pressure was made around the joint or the limb moved in any direction. Two inches below the upper border of the great trochanter a sinus opened. A probe passed through this touched dead bone in the neighborhood of the joint. As the boy was losing flesh, it was decided to excise the joint. The operation was performed under Lister by an incision just through the walls of the sinus, and afterwards through the tissues two inches above and posterior to the great trochanter. The diseased head of the femur was removed as well as a small portion of the acetabulum. Twelve hours subsequently the temperature rose to 102½°, pulse 125. Since then pulse and temperature gradually lowered, approximating more nearly to the normal standard. No bad symptoms of any kind had exhibited themselves up to the present time. Two weeks after the operation the temperature was normal and the pulse 104. The increase in the pulse he attributed to the use of stimulants. He attributed the absence of unfavorable symptoms to the antiseptic treatment.

STRANGULATED HERNIA.

Jacob Dackerman, *æt.* 45, was admitted to St. Francis' Hospital, April 10th, suffering from a strangulated femoral hernia. The hernia was nine years old, and caused no inconvenience until four days previous to admission. At that time the hernia became tense and painful, and there was some nausea, but no vomiting. On the fourth day he was admitted to the hospital. He complained of but little pain. Food given him was thrown up, but otherwise his stomach was not disturbed. The day following his admission Dr. H. saw him for the first time. He was then in a state of collapse, and rapidly sinking. Dr. H. opened the sac, and found a large quantity of omentum thickened and congested, and a small knuckle of intestine approaching gangrene. The stricture, which was a Gimbernat's ligament, was cut and the intestine returned. The omental portion of the tumor was cut off, and the stump returned to the abdomen. Death took place six hours after the operation.

The principal point of interest connected with the case was the absence of stercoraceous vomiting and the other characteristic signs of strangulation, which caused the physician in charge to underrate the gravity of the case.

FIBROID PHTHISIS—INTRA-PULMONARY RÂLES.

DR. BEVERLEY ROBINSON presented a specimen, of which he gave the following history and remarks: "The lungs I desire to show you are such as one

finds frequently in the post-mortem room. They are specimens manifesting, in a very evident manner, the lesions of fibroid phthisis. You will remark, however, one or two facts. In the first place, both apices are riddled with cavities, and the walls of these cavities are particularly hard and dense, owing to the great amount of fibrous tissue present. Over the anterior surface of the left lung, in the region of the apex, the pleura is extremely thick. And so intimately adherent one to the other were the visceral and parietal layers of this region that, at the autopsy, they both had to be brought away with the left lung when it was removed from the chest. Now, just before death, this lung was examined by auscultation, and at the level, where the intimate pleural adhesions are seen, there was revealed a large number of fine moist râles. For me, therefore, here is an example which is unimpeachable, where the râles are intra-pulmonary, and not intra-pleural; and, moreover, as the intra-pulmonary condition appears to me of older date than that of the pleura, I believe the pleuritic adhesions followed the fibroid phthisis, and were not the cause of the latter. In view of late important and interesting discussions in regard to "a new classification of phthisis," and also in regard to peculiar views held by the author of that paper about intra-pleural râles, my specimens are not devoid of interest."

A CHIP OF BRASS IN THE CILIARY BODY.

DR. KNAPP presented an eyeball which he had removed a few days previously. Six years ago a piece of brass had entered the patient's eye through the cornea and lens. After the mild inflammatory symptoms which followed the injury had subsided, the eye gave no trouble for six years. Then suddenly it became so painful and inflamed that it was removed three days after the pain had set in.

The eyeball, opened by an equatorial section immediately afterward, showed the vitreous perfectly clear, though watery; in the posterior part of the retina, a gray scar, a patch of connective tissue of about 2''' in diameter; the retina everywhere in its proper position. Embedded in the ciliary processes at the bottom of the eye lay a chip of bright metal, 3''' in length; no connective tissue around it; no inflammatory exudation worth mentioning. From the history of the case, and the autopsy of the enucleated eye, Dr. Knapp thought that the foreign body must have lain encapsulated in the retina for six years, but recently worked itself loose, dropped through the vitreous upon the lowest part of the eyeball, the ciliary body, in front of the inferior rectus muscle, in which locality the foreign body had been found.

PLASTIC CYCLITIS.

DR. KNAPP presented another specimen—an eye with a dense white pseudo-membrane lining the inner surface of the ciliary body. The eye had been removed from a girl twelve years of age. It had been affected by chronic inflammation for a year; and, when Dr. Knapp saw her first, the symptoms of iridocyclitis were so marked that the sightless eye, threatening the other by sympathy, had to be removed.

TUMOR OF PONS AND MEDULLA.

DR. G. L. PEABODY presented a specimen of tumor of the pons and the medulla, with a history as follows:

Mrs. A., *æt.* 54 years, was an active, well woman up to March, 1878. Then, after a fall, she often complained of weakness in her legs. In May, 1878, she had obscure symptoms from her head and limbs, of

which nothing was definitely known. In October, 1878, she came under the treatment of a physician in Boston, who had kindly given a few notes of her case. She then complained of dull headache, mostly at base of brain, slight loss of motion in arms and legs, but no loss of sensation. At the end of October she suddenly fell to the floor without apparent cause. She was obliged to remain in bed four weeks at that time, owing to marked loss of power in her limbs. She was treated by ergot and potass. sod., and improved. The headaches continued as before, but were at times relieved by potass. bromid. At times these headaches were intense. By the middle of December she was greatly improved, being able to write letters, go up and down stairs, and attend generally to duties of life. All this time she still had slight difficulty in raising her feet.

On the 31st of December, 1878, she was brought to the New York Hospital, having made the journey from Boston on that day. She was found dead on reaching the hospital, and had probably been dead about two hours. She had walked that morning to her carriage on going to the railway station.

At the autopsy a tumor was found on the right side of the pons and medulla, and making a deep impression in the cerebellum. Roughly speaking, it was an oblate spheroid in shape, with a diameter of one inch and a half, and an axis of three quarters of an inch. The 5th, 6th, and 7th nerves of that side were compressed by it and considerably reduced in size. It was intimately adherent to the bone, the dura mater having been eroded by it and disappeared. The bone was also eroded by it. The tumor and brain tissue were nowhere intimately adherent. It was soft to the touch, and grayish-red in color, and nowhere gritty or sandy to the touch. On microscopical examination it was found to be a sarcoma, such as was not uncommon within the cranium. It contained many blood-vessels of large size, and was made up chiefly of spindle cells, with some round cells.

ANEURISM OF THE ARCH OF THE AORTA.

DR. M. J. MESSEMER presented a specimen of aneurism of the arch of the aorta, accompanied by the following history:

John T. Morris, *æt.* 39 years, carpenter, came to him at the out-door department of the Mt. Sinai Hospital, on the 25th of March, 1879. When he entered, a peculiar wheezing sound accompanying his breathing was distinctly noticeable at some distance from the patient, which became more marked as he spoke. He stated that in October, 1878, he was eating an apple while walking along the street, and a seed of the apple entered his larynx. A short time thereafter he experienced shortness of breath. Dyspnoea was especially apparent when he reclined on his back, mounted the stairs, ran, or exerted himself; he had, however, experienced no pain in the chest at any time since then.

On examining him, with Drs. Sanders and Wardwell, the manubrium was found somewhat depressed, being about one-quarter of an inch lower than the body of the sternum. There was a pulsating elevation or tumor immediately to the right of the sternum, about the second intercostal space, several inches in circumference.

On percussion, dulness was revealed over this elevation or tumor. Pulsation could be felt with the hand and was quite apparent to the eye. Slight tympanitic sound was found with the vesicular resonance over the entire thorax. On auscultation a distinct pulsating sound was heard over the region of the tumor. No

valvular lesions existed. Expiration was somewhat prolonged and inspiration slightly shortened. In the interscapular region intensified heart-sounds were observed. On laryngoscopy the patient, he found the vocal cords intact and the larynx and pharynx normal.

On pressing the finger downward behind the top of the sternum, a strong pulsation was distinctly recognized.

Laryngoscopy revealed normal vocal cords. Diagnosis: Aneurism of the arch of the aorta. He administered ten grains of the iodide of potassium three times a day. March 28th: Patient reported greater facility in breathing, and, when speaking, wheeziness was not so apparent as before, but physical signs remained the same. Same treatment continued. April 1st: No change in symptoms. Treatment the same. April 4th: Noticing no further improvement, prescribed infus. of ipecac. ʒss. to ʒviij. April 8th: Patient reported further improvement; administered infus. ipecac., with Fowler's solution, five drops, and iod. The patient returned on the 10th, stating that he felt better, and that his breathing was much relieved, but that he had expectorated small quantities of blood at intervals of every ten to fifteen minutes since the 8th. He expectorated in the doctor's presence several times, and each time blood of a bright red hue was apparent in small lumps, about the size of a bean, with the mucus. He administered morph. acetat. and infus. ipecac., but the patient expired on the following morning at 4 o'clock. His attendant stated that he had been awakened by a noise, as though something was being torn in his chest; immediately thereafter the patient vomited about four quarts of blood, stated that he felt his end approaching and immediately expired.

Autopsy (made Saturday afternoon, April 12th, at two o'clock, thirty-four hours after death, by Dr. Sanders and himself) revealed slight pleuritic adhesions of right pleura. Lungs congested and inflated in appearance. Alveoli dilated. No consolidation in any part of the lungs. (Esophagus intact, and in order. Mucous membrane of the bronchi presented a roughened appearance. The heart structure was normal. The arch of the aorta and upper portion of the descending (thoracic) aorta were distended. Some of the valves were destroyed in effecting a larger opening into the arch of the aorta, so that the aneurismal sac could be better inspected. A quantity of fibrin was detected in the aneurismal sac, and the rupture was found to have taken place into the right bronchial tube about an inch above the bifurcation. The opening caused by the rupture was well marked in the specimen presented. All other blood-vessels connected with the heart or aorta were normal.

The stomach was distended with blood.

The liver and spleen were normal in size, but slightly congested.

Both kidneys showed slight congestion, and there was an infarction in the cortical substance of the right kidney, in the centre of its outer border.

Very little blood was found in the thorax, which small amount might have escaped while the post-mortem was being made.

After rupture occurred, the blood escaped through the right bronchial tube, trachea, and larynx into the mouth, and was mostly ejected in that manner, some, however, running through pharynx and oesophagus into the stomach. The dyspnoea was due to the pressure of the aneurismal sac upon the bronchial tube.

FILARIA FROM THE EYE OF A HORSE.

DR. H. D. NOYES showed a filaria which he had removed from the anterior chamber of the eye of a horse

on the day previous. The parasite was first seen in January, and was visible three days. It then disappeared from view for six weeks, and since then, while often visible, it would not be discoverable for several days or hours.

The creature, as seen by Dr. Noyes, was running actively about the anterior chamber, and the horse did not evince any consciousness of suffering. There was decided opacity of the cornea and some circumferential hyperemia. The removal was done to prevent increase of corneal opacity. The horse was supposed to be twelve years old. Those filariae were common in the peritoneal cavity of the horse, and occasionally appeared in the eye.

At the operation, which was done with the help of Dr. Liautard, at the American Veterinary College, the horse was thrown and etherized, the cornea punctured with a lance-knife, and the wound held open as the point was partly withdrawn, so as to cause the aqueous humor to spurt in a gush. The parasite was thus driven out, and lived for an hour after its extraction. It measured two and a quarter inches, or fifty-eight millimetres, in length. Its neck was curved into a spiral, forming one and a half turns, and at the extremity of the head was a minute papilla, from which the name *filaria papilli fornix* was derived.

Dr. Noyes explained the disappearances of the filaria by supposing that he went through the pupil behind the iris, but did not penetrate into the deeper part of the eye. Since the specimen was presented, the horse had been heard from: the eye recovered from the operation, and the opacity of the cornea had begun to fade away.

Correspondence.

VISIT TO BERLIN.

THE EIGHTH ANNUAL MEETING OF THE CONGRESS OF GERMAN SURGEONS—MARTIN'S OPERATION OF EXTIRPATION OF THE KIDNEY—SCHROEDER'S OPERATION OF EXTIRPATION OF THE UTERUS.

By J. MARION SIMS, M.D.

THE eighth annual meeting of the Congress of German Surgeons was held at Berlin from the 16th to the 20th April. The meeting, under the presidency of Langenbeck, was largely attended, and every moment of time was profitably occupied. Billroth, Esmarch, and most of the German surgeons whose names are familiar to us, were there, except Volkmann and Négar. The first was in Italy, the other unavoidably detained at home. The morning meetings, from 9 to 1, were held in the amphitheatres of different hospitals, and were devoted to clinical demonstrations and discussions. The afternoon sessions, held at the University, were devoted to the reading and discussion of papers. I went to Berlin as much for sight-seeing as for the interest I felt in the surgeons and surgery of Germany. I shall not, therefore, write you anything like a synopsis of their doings, but will give you a few items that incidentally came under my observation.

EXTIRPATION OF THE KIDNEY.

You remember how we were all electrified, about ten years ago, with the news that the daring, dashing Simon had successfully extirpated the kidney. I do not know how often Simon's operation has been per-

formed; but at home I know that it was done successfully by the late Dr. Gilmore, of Mobile, and by our own George C. Peters. It has remained for Dr. Martin, of Berlin (son of the late Prof. Edward Martin), to open up a new field for and a new method of doing this operation. He has now extirpated the kidney five times—four times successfully. And, strange to say, he has done the operation for what is known as floating kidney. His operation before Listerism would have been wholly unjustifiable. But now it is justified by its simplicity and its success. It is as simple, if not as easy, as ovariectomy, and quite as successful. Certainly so in Martin's hands. I had the satisfaction of assisting at Martin's fifth operation, on the 19th of April. The operation is by abdominal section. Instead of using a single table, five feet long, for his operations, he has two tables, each about two and a half feet long, end to end, one being a little lower than the other. The patient was chloroformed in her own chamber, and then brought into the operating-room, and placed on the table, with the head to the window. The head was on the lower table, the pelvis on the higher one. The head was placed low, with the intention of preventing syncope, the chief source of danger in the use of chloroform. Martin's spray-apparatus is an enormous affair that will work for hours. It was placed six feet or more from the patient, and the spray passed over the assistants, and fell on the patient, not in a dense cloud, but in a sort of mist. It seemed to me to be "too much of a good thing."

The operation was begun at ten minutes to 8 A.M., and was finished in twenty-six minutes. It was done slowly and with great painstaking. The incision was begun about two inches above the umbilicus, and extended two inches below it. The bleeding from the edges of the abdominal wound was arrested, as in ovariectomy, with hæmostatic forceps. The peritoneum was then incised. Some folds of small intestine protruded, and were pushed back and retained by a carbolized sponge probang. The kidney was then pushed to the abdominal incision by pressure on the loin behind, where it was seized with a vulsellum, and securely held. The peritoneum investing it was then opened longitudinally; and the kidney was enucleated and brought freely into the peritoneal cavity. Some large veins on its surface were ligated, and its attachments (consisting of renal artery, renal vein, and ureter with cellular investments) were tied in sections, just as we secure a broad pedicle in ovariectomy. The pedicle (so to say) of the kidney, necessarily running longitudinally with the kidney, about three fingers' width long, was transfixed, and tied with five separate ligatures. The kidney was then neatly dissected away from the pedicle and removed. The pedicle was dropped back into its proper place behind the peritoneum; the peritoneal cavity was then carefully sponged dry; and the external wound was closed with interrupted sutures. The sutures and ligatures were carbolized silk. Antiseptic dressings were applied, and the patient removed to her bed.

I saw her twenty-four hours after the operation. Her pulse, temperature, and expression were good; and I thought she would in all probability recover. But I have since heard from Dr. Martin that she died of peritonitis three days after operation. All of Dr. Martin's operations have been done for floating kidney. Heretofore we have told our floating-kidney patients that they must accept their condition as incurable. Whether we will readily follow the bold example of Dr. Martin, and extirpate floating kidneys hereafter, is a question.

Dr. Martin had his last case under observation four or five months. He had failed to relieve her sufferings in the least. She complained of weight and pain in the kidney; could not work; and yet was obliged to work to make her living. Having exhausted all other means of relief, he proposed the operation, laying before her and her husband its dangers. After due deliberation, they determined to have the operation, being greatly encouraged by the fact that Dr. Martin had already performed it successfully four times.

Dr. Martin says that in one of his cases he had great difficulty in completing the operation. The patient was fat, the abdominal walls loaded with fat, and it was necessary to make a transverse incision to the right from the median line. The kidney was then safely removed; but the first dressing of the wound, a day or two after operation, showed that the transverse incision had failed to unite; it gaped widely open, and for two or three days afterward the liver could be seen at each dressing, moving up and down with each respiratory act. Notwithstanding all this, the patient recovered without a bad symptom.

We all remember Dr. Miller, of East Broadway, who died some ten or twelve years ago, worn out with kidney disease, complicated with abscess and stone in the pelvis of the kidney. He was an able physician, one of the best of men, loved by his friends and patients, and greatly respected by his confidères. When I first knew him, I too was in bad health, hardly expected ever to recover, and my sympathies were naturally drawn to him. His manly form was bent, and his genial face furrowed with the lines of suffering, as he worked bravely on to the last for the relief of the suffering of others, without the least hope of relief for himself. In such cases as this there is certainly a future for Martin's operation. In such a case as this we might cut down on the kidney, as Martin does, and if we found a stone in the pelvis we could remove it, close up the incision with suture, return the kidney to its place, and leave the case to nature's efforts.

CHOLECYSTOTOMY FOR REMOVAL OF GALL-STONES.

In my paper on cholecystotomy, published a year ago, I urged the propriety of cutting down on the liver, for the purpose of removing gall-stones from the gall-bladder. This operation was done recently by Mr. Bryant, of Guy's Hospital, and the case was to be brought before the Clinical Society of London last week. Mr. Bryant told me a few days ago (May 8th) that the operation was successful, and his patient cured. With the lights now before us, there is no reason why we should not do the same thing for the kidney, if done with antiseptic precautions.

EXTIRPATION OF THE UTERUS.

The name of Schroeder is well known amongst us. We are all familiar with his classic work on gynecology and with his great success as an ovariectomist since his adoption of Listerism. He is yet a young man, with a splendid record and an assured brilliant future. I saw in his wards an interesting case of extirpation of the uterus for sarcoma.

The operation had been performed about ten days before, and the patient was convalescent. She was nearly forty years old, and had a tumor about the size of an egg in the body of the uterus. A bit of it was scraped out with the curette, submitted to the microscope, and found to be malignant.

Prof. Schroeder then determined to extirpate the organ. He made the incision as for ovariectomy; drew the uterus up from the pelvis; transversed the

cervix with a double ligature antero-posteriorly, just above the vaginal junction; tied one on each side, including the corresponding part of the broad ligament, just as Péan does; and then he amputated the body of the uterus from the cervix at the os internum. This left a raw surface about an inch and a half in diameter, which Péan and others have been in the habit of pulling outside through the lower angle of the abdominal incision, and fixing it there, as they did the pedicle in ovariectomy. The clumped pedicle and Listerism are antagonistic, if not incompatible. Prof. Schroeder did not wish to leave a sloughing pedicle outside; nor did he wish to leave a suppurating one inside the peritoneal cavity. And he hit upon this happy idea. He excised the cervix conically from the amputation surface down to the point at which it had been transfixed with the ligatures; and then he brought its thin edges together antero-posteriorly, and secured them with fine interrupted carbolized silk sutures. Thus the incised surfaces were brought into contact internally, leaving only serous surfaces in contact in the peritoneal cavity. It was beautiful in theory and successful in practice; for the patient recovered, with the pulse and temperature remaining very nearly normal all the time.

LITHOLAPAXY.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—An editorial paragraph in the RECORD of May 31st mentions that the letter from Sir Henry Thompson to Professor Van Buren, which appeared in the previous issue, was written for publication.

Sir Henry's reiterated criticisms of lithotrites should not be allowed to obscure the main facts, be their value more or less, of Rapid Lithotripsy—which means long sittings for the immediate and complete evacuation of the fragments by large tubes, and depends upon the newly discovered tolerance of the bladder to the smooth surfaces of instruments—while the old lithotripsy meant repeated short sittings and sharp fragments left in the bladder.

The size of a lithotrite has little to do with litholapaxy. Stones are so frequently soft and small that a small lithotrite of any kind may be often large enough. Of course the operator will be careful not to break such a lithotrite upon a large or hard stone. Like other lithotrites, mine is made in various sizes. It is not a large lithotrite that I have desired to bring to the attention of surgeons, but a new lock, with protective and non-impacting blades—designed to promote safe and rapid work at a moment when the hand or the attention of the operator is fatigued by a long operation. I prefer a large lithotrite, if it possesses these qualities, even in dealing with common calculi. Sir Henry prefers a smaller one, and frequently withdraws it to clean it. His prejudice against a large instrument is connected with a life-long and erroneous theory that the dangers of lithotripsy result mainly from the instruments used in the operation. This was the general mistake of the day. It was not known that the irritation was really occasioned by the fragments which it was the custom to leave in the bladder. When these fragments were drawn out by my apparatus, and that source of danger to the bladder was removed, it was found that the instruments themselves did but little harm. Sir Henry, perhaps, might long ago have discovered this fact of the tolerance of the bladder to instrumentation, if he had possessed any means of evacuating it thoroughly. But he had only Clover's instrument,

the tube of which was so small (21 French) that it drew out only sand, and left the fragments. Hence his error, and failure to discover the new facts of what is now known as rapid lithotripsy.

Sir Henry devotes the last half of his letter to the expression of erred sentiments in relation to his attitude towards surgical progress. A little explanation may be here desirable.

A year after the publication of my paper he published a lecture in the *Lancet* (February 1, 1879), in which he says, "My own system has for a long time past been gradually inclining to the practice of crushing more calculus at a sitting, and removing more débris by the aspirator than I formerly did," which might very well be true, his former sittings having been limited to two minutes or less; but the hindrance to his "removing more débris" was the small size of Clover's tube. The editor of the *Lancet* replied (February 15), "We cannot close our eyes to the fact that the views advanced in his lecture of the 1st inst. do involve an abandonment of his old position. Lithotripsy as hitherto practised by him, and lithotripsy as recommended and performed by Professor Bigelow, are different operations, and based on opposite and contradictory principles." This "editorial observation" in the *Lancet* Sir Henry, curiously enough, chooses to regard, in his letter published in the RECORD, as "adverse criticism of himself personally, not of his mode of operating."

In this connection Sir Henry expresses the opinion that the terms "abandonment of position," and the like, "adapted, as they are, to military men," do not accord with the aims of men who "live and learn." . . . "It is an error," he says, "to look for a life-long consistency in matters of opinion from men who think for themselves." The world will not question the right of Sir Henry to "live and learn," nor to "think for himself," but only the propriety of his claiming to have originated by "thinking for himself" ideas he has learned from others.

A friend has to-day sent me the fifth edition, just published, of Sir Henry's "Diseases of the Urinary Organs." I find that in this edition Sir Henry both honors Rapid Lithotripsy with his indorsement and appropriates as his own its essential details.

He adopts large tubes, increasing the ineffectual catheter of Clover from 21 to 29, which latter calibre I often employ, my usual size being 30, and my largest 31. "You are first to introduce," he says (p. 173), "an evacuating silver catheter fitted with a flexible stylet—in size, say, from No. 14 to No. 16, English scale: "calibres equivalent to 24 and 29 French.* Here being the essential feature of the operation, Sir Henry at this point definitively abandons "consistency" and the 21 tube of his previous editions, in favor of "large evacuating catheters and a good aspirator" (p. 177). Neither of these he used before I described them. This gives him the key to Rapid Lithotripsy, and he is able to accomplish thorough evacuation at once by prolonging the sitting till evacuation is complete, demonstrating at the same time that the bladder toler-

* Handerson's comparative scale, from which these equivalent numbers are taken, is made by Reynolds & Co., New York. It is accurate, and very convenient in having, instead of holes, a long triangular slit like a wire gauge. "In England," says Sir Henry Thompson, we cannot be said to have a uniform scale; all our measurements are very arbitrary. One maker has one scale, and another another." ("Diseases of the Urinary Organs," 1879, p. 47.) On page 48, however, he gives a scale, of which the largest size, 14, is the equivalent of 24; and this corresponds to Handerson's Scale. (New York Medical Record, 1877, p. 678.) The French numbers increase more rapidly than the English. Larger calibres have hitherto been but little known either in France or England. The main point is the necessity of enlarging Clover's tube.

ates instrumentation, if the fragments are removed—which is the new principle that underlies Litholapaxy. The large tube once appropriated, the rest is easy. The aspiration of his new edition means effectual aspiration with large tubes, and his Lithotripsy becomes Rapid Lithotripsy.

A comparison of this, Sir Henry's present practice, with his recent opposite teaching of frequently repeated crushings—each confined to a few minutes, lest the instrument injure the bladder, but leaving the bladder nevertheless to struggle, in the intervals, with debris which he had no means of extracting—will show the significance of the criticism by the editor of the *Lancet*.*

In conclusion, I may venture to hope that the valuable example set by Sir Henry in accepting large tubes will aid in doing away with whatever apprehension still exists of danger from their use.

HENRY J. BIGELOW.

BOSTON, MASS.

EMPYEMA TREATED BY ASPIRATION AND BY OPEN INCISION, WITHOUT INJECTIONS.

BY JAMES J. HEALY, M.D.,

AND

E. P. HURD, M.D.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—Two cases of empyema, under the care of Dr. J. J. Healey, have terminated successfully: the first after two aspirations with a Dieulafoy aspirator; the second, after making a permanent opening into the thoracic cavity, from which pus exuded almost constantly for more than a month.

CASE I.—J. C., aged 40, unmarried; an intemperate man; day-laborer by occupation; broken down by bad habits. Came under Dr. Healey's care in January last. The patient suffered for some ten days from fever, with pain in right chest, dyspnoea, and prostration; fever assumed a hectic type, with profuse sweats. Dr. E. P. Hurd was called in consultation. The diagnosis of the attending physician—pleurisy of the right side, with effusion—was confirmed, and the necessity of immediate aspiration concurred in. Pulse was then 130; fever-heat 103; respiration 40 per minute, and performed with much distress. There was decided bulging of the thorax posteriorly and in right infra-axillary region, and dullness all over the base of right lung, and loss of respiratory movement and murmur. Respiratory sounds on the left side were normal, but exaggerated. The patient could lie only on the affected side.

The aspirator needle was introduced between the eighth and ninth ribs, on a line with the inferior angle of the scapula, and a pint of laudable pus withdrawn. This gave great relief to the patient, who commenced forthwith to mend. The aspiration was repeated the week following, but only a few ounces of pus were withdrawn.

The subsequent history of the patient is one of uninterrupted recovery.

CASE II.—The treatment of this case coincides in a marked manner with that of Prof. Post, recorded in the RECORD for April 5, 1879. It illustrates the safety with which, in cases of empyema, a permanent opening, whether by knife or trocar, may be made into the thoracic cavity.

M. D., a child of three years, was taken ill with pleurisy about the 1st of February. Dr. Healy saw the patient about the 14th, and diagnosed pleurisy with effusion. Pulse 110; respiration 48; temperature 103°; decided bulging of right side; left laboring heavily; right side almost motionless; patient lies on the sound side and back; dyspnoea; marked hectic.

Percussion indicated great dullness over whole of right chest, front and back, below level of nipple; left lung was abnormally resonant throughout. Auscultation gave no respiratory sound over right base; on the left side the respiratory murmur was puerile. Above the line of dullness, on the right side, there was bronchial breathing.

Dr. E. P. Hurd saw the patient in consultation, and concurred in the diagnosis and the mode of treatment demanded. At this time the pulse was 160 and feeble, and the dyspnoea was extreme. The aspirator needle was introduced between the seventh and eighth ribs, just in front of their angle, and eight ounces of laudable pus were removed, to the great relief of the little patient.

On March 4th the aspiration was repeated, the right chest being full of fluid, and the dyspnoea being urgent. Thirty ounces of pus were withdrawn, with signal relief to the suffering child.

On March 7th, the pleural cavity being again oppressed by a purulent collection, Dr. Healy made a permanent opening between the ninth and tenth ribs, on a line with the inferior angle of the scapula, dissecting his way into the thoracic cavity with a common bistoury: a gush of matter followed, which was somewhat fetid. A fistulous opening remained, which only required to be occasionally cleared out by means of a probe. Carbolic dressings were applied. Pus flowed intermittingly for more than a month. By April 15th it had ceased to run, and the fistulous opening closed. Some little deformity ensued by retraction of the ribs of the affected side; but the lung has been fast regaining its normal position and function. The child is now apparently as well as ever.

NEWBURYPORT, MASS.

GRINDELIA ROBUSTA IN RHEUMATIC AFFECTIONS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Some time ago I noticed in several of the medical journals suggestions as to the use of *grindelia robusta* in asthmatic affections. I took occasion to make use of this remedy, and found that although in some cases a certain degree of benefit was perceptible, yet it by no means equalled the results I had been led to anticipate. The thought occurred to me that it might be well to couple with it some preparation of *yerba santa*, this having acquired considerable reputation of late in the treatment of bronchial affections. Accordingly, the next time asthma was submitted to my care, I prescribed as follows:

℞. Elixir *grindelia robusta*..... ʒij.
Glycerole of *yerba santa*..... ʒiv.

M. et Sig. from two teaspoonfuls to one tablespoonful four times a day.

The result exceeded my most sanguine expectations, and I will give the brief details of three cases:

CASE I.—Mrs. L. M., aged 37, had suffered from asthma fifteen years. During this period she, like almost all asthmatics, had tried many remedies with

* The *Lancet* of May 17 contains a letter on this subject.

no practical relief. Coming to me August 4, 1878, I gave her the medicine to which I have just referred. Before commencing treatment she was robbed of the latter part of almost every night's rest. About two o'clock in the morning the sitting posture, and the smoking of a preparation for the relief of dyspnoea, became imperatively necessary. The loss of sleep consequent upon these procedures had their legitimate effect upon her system. Emaciation and general debility followed, and her careworn and anxious countenance plainly indicated the suffering she was undergoing.

The first night the medicine was taken refreshing sleep till six o'clock in the morning resulted. From that time to the present she has not lost a night's rest from this cause, nor felt more than a very slight indication of a return of asthma, notwithstanding she has suffered in the interim several times with a severe cold. She has gained flesh, is much improved in general health, and says the medicine has been and is to her of invaluable worth.

CASE II.—Mrs. L. P., aged 32, was an asthmatic for ten years. Emaciation was very marked, her rest habitually broken, and her bowels were obstinately constipated. Coming to me November 4, 1878, I gave her the *grindelia robusta* and *yerba santa*. During the first two days the relief was slight, but improvement then became decided. At this juncture the breaking up of housekeeping caused a severe and continued cold, and her asthma became nearly as bad as ever. The remedy was continued, however; the patient recovered from the attack, and has not felt any indications of a return of her malady up to the present date. Her bowels have become regulated, and her general health and emaciation very much improved.

CASE III.—Mrs. A. V., aged 50 years, an asthmatic for eighteen years. She had been so intense a sufferer as to become a confirmed morphine eater; she commenced the treatment already referred to December 4, 1878. Immediate and (up to the present time) permanent relief was obtained. I would remark, incidentally, that her morphine habit has also been cured, and I regard the manner in which it was accomplished of sufficient interest to merit passing mention. Her husband invariably purchased the drug for her; I took advantage of this fact to empty the contents of a bottle of morphine, extract a little of it, and substitute in its stead the same quantity of quinine. After mixing them thoroughly, they were carefully replaced in the bottle, and Mrs. V. kept in ignorance of the change. During the first few days her symptoms were very distressing and even alarming. Recovery, however, soon occurred, and every time morphine was purchased I lessened its quantity and increased the quinine until at last she was taking clear quinine. At this juncture the deceit was made known to her, and inasmuch as she had not suffered from asthma for a long period her good sense impelled her to discontinue the use of both morphine and quinine.

From the gradual reduction in the quantity of morphine and the similarity in the taste and appearance of the two drugs her suspicions were not aroused. With the exception of a few days during the latter part of the treatment, she made no complaint of tinnitus aurium; and the quinine, acting as a tonic, to a large extent improved her general health.

I think this case is interesting, not only as regards the relief from asthma, but from the possibility in this manner of breaking up the morphine habit.

It is not necessary to cite more instances; those already given are but fair illustrations of other cases

in which I have used the remedy. I have prescribed it about twenty times, and in only two instances (and these were cases of a very complicated nature) where patients have followed my directions has it failed in producing good and (up to the present writing) permanent results. After the medicine has been taken in large doses for a few weeks the quantity may be gradually reduced, and at last altogether discontinued. I have noticed in some cases that considerable nausea and looseness of the bowels were temporarily produced.

FRANK ALLPORT, M.D.

SYCAMORE, ILL., May 24, 1879.

“TREATMENT OF OBSTINATE VOMITING BY SMALL DOSES OF IODIDE OF POTASSIUM.”

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Having noticed in the RECORD of March 15th, under the above heading, an article taken from a statement made by Dr. Formica Corsi in the “Gazette Obstetricale,” and having a patient suffering from obstinate and intractable vomiting arising from spinal inflammation, and having exhausted all the remedies ordinarily employed as anti-emetics, without the least amelioration in the symptoms, I determined to try the iodide in the minute doses recommended by Dr. Corsi. The vomiting had occurred immediately after taking food of any description, quantity and quality making no apparent difference. Vomiting occurred with very little effort, nausea persisting for only a short time after the contents of the stomach had been entirely rejected.

This state of things had existed for at least two months, in which time she had retained only an occasional mouthful of food.

After the use of injections of beef-tea and egg for several days, during which time nothing but a little drink was allowed by the stomach, one or two meals were retained, but the vomiting commenced again, and continued up to the time of the administration of the iodide. I gave it in solution, in doses of $\frac{1}{8}$ grain, repeated every hour and a half; and since then—now fourteen days—she has retained everything she has taken, excepting one or two meals, when she had omitted the drug for a few doses, at my request, as a test.

Respectfully yours,

GEORGE HUNTINGTON, M.D.

LA GRANGEVILLE, N. Y., May 4, 1879.

New Instruments.

A REMOVABLE PAPER BRACE FOR THE TREATMENT OF POTT'S DISEASE AND LATERAL CURVATURE.

By AP. M. VANCE, M.D.,

OF NEW YORK.

THE use of paper in the treatment of spinal disease first suggested itself to me while a student in the University of Louisville, in the summer of 1877. During the year preceding I had been using the plaster jacket in all forms of spinal disease. The chief objections to the plaster, viz., its weight, imperviousness, liability to break down easily, necessitating frequent reapplication, and the difficulty of removing the same. I thought might be overcome by some removable dress-

ing, which secured the same support and at the same time would prove to be far more durable. I had seen in the practice of Dr. Cowling the use of the paper in fracture splints, with results in every way satisfactory.

The great obstacle in the way of using the paper for the spine was, that it could not be applied directly to the body, on account of the time required for hardening, and the yielding of soft parts. A smooth dressing without wrinkles was next to impossible. To overcome this objection, I first constructed the brace over a plaster-jacket which had been removed from the body. The jacket thus made being, of course, somewhat too large, a vertical section was removed in front and behind; the parts then being brought together and laced like a corset.

This division was deemed necessary, as it was not supposed that the dressing would be elastic enough to open sufficiently to admit the patient's body without breaking. After two or three attempts this was found to be quite superfluous. The jacket made over the plaster, itself not an accurate cast of the body, necessitated padding at different points in order to secure an easy fit. It occurred to me then that the plaster-jacket first taken, might be filled with the mixture of plaster, and this having been allowed to set, the external jacket then removed, a perfect cast of the body could be obtained. This was easily accomplished and a perfect fit secured. Up to this time I had been using the egg and flour paste, but the hot weather effected such changes in this, that a disagreeable odor was developed. In connection with Dr. Vincent Davis, a prominent chemist of Louisville, I experimented with the view of obtaining a glue, as a substitute for the paste, not open to the above objections. A mixture of white glue and oxide of zinc we found to answer the purpose admirably.

Dr. D. W. Yandell, whose student and assistant I was at that time, early recognized the superiority of the paper over the plaster-jacket, and adopted this in the treatment of all spinal cases. These were under my own immediate care, and I take this opportunity of publicly thanking my preceptor for the opportunities he afforded me of testing the appliances thus constructed. The practice thus afforded me in Dr. Yandell's office and at his clinics extended over a period of nine months, and I had abundant clinical material on which to make observations.

In the beginning of 1878, one of his patients, wearing the new paper brace, visited Chicago, and there came under the observation of Dr. Edmund Andrews, who was so favorably impressed with the dressing that he wrote to Dr. Yandell for a description of its construction. By request, I wrote a description, which was forwarded to Dr. Andrews, who has recently made reference to its advantages in the April No. of the *Chicago Medical Times and Examiner*. In the spring of 1878 I gave a demonstration of its construction and application before the Kentucky State Medical Society, then in session at Frankfort. About the same time, at the request of Dr. Lewis A. Sayre, I forwarded to him a jacket and head-spring complete, accompanied with a full description. In a letter under date of May 19, 1878, acknowledging its receipt, he makes two objections, viz., imperviousness and cost, which I shall refer to at the conclusion of this paper. Since that time I have used the brace in my own practice at Louisville, with such modifications and improvements as have suggested themselves to me from time to time. The most important changes were the introduction, between the layers of paper, of narrow, vertical steel springs, adding greatly to the strength of the brace, and enabling me to dispense with several

additional layers of paper, thus greatly diminishing its weight and bulk; extensive perforation of the brace, which thus secured ventilation without materially diminishing its strength; and further modifications in a manner to be hereafter described, to make it efficient in lateral curvature. The method of making the brace is as follows: An ordinary plaster-jacket of good length is first applied, especial care being necessary to secure a smooth inner surface. By adding a tablespoonful of alum to the quart of water used, the plaster can be made to set much more quickly, so that it can be removed almost immediately. This is done by cutting down in front. Having brought the cut edges together and fastened them with twine, the jacket is placed on a table and made water-tight by plastering around the base and up the incision in front.

The plaster mixture, of the consistency of thick cream, is now poured in until full. By partially filling with bricks, before pouring in the plaster, much less will be needed. In ten or fifteen minutes the external jacket can be removed. This must be done with care. Any slight irregularities in the cast must be smoothed off with a knife. Thus prepared, it is thoroughly greased; the object being to confine the moisture still in the plaster, which might otherwise greatly retard the drying of the paper-jacket. Over this an ordinary roller is applied, which separates the jacket from cast, thereby protecting it from the grease, and giving a smoother surface.

Then canton flannel fitted smoothly over it, by tightly stretching, and secured by seam in back, forms the inside of the brace. To this the glue is applied with a brush. The following is the formula used: White glue, one part; oxide zinc, two parts; hot-water, six parts. Dissolve the glue in the water, and add the oxide of zinc, which should be finely pulverized. This will keep indefinitely, and is ready for use on reheating. Brown manilla paper of moderate weight—such as is used by mechanical draughtsmen—is cut in strips one and a half inch wide, long enough to reach a little over half-way around the cast, and applied horizontally, beginning at bottom of back, lapping each strip half-way; each strip having been previously coated with the glue. Having finished the back, cover the front in the same manner, lapping ends at sides, so as to give additional strength where most needed. Narrow steel-springs—those in ordinary hoop-skirts will answer—cut a couple of inches shorter than the cast, are placed vertically at intervals of one and a half inch; these being made to fit to the cast accurately by wrapping around the whole strong linen thread. Then another coating of glue, and the second layer of paper strips; this time being placed vertically, and lapping as before. A few turns of thread around this will secure accurate adaptation; over this another coating of glue, and lastly a roller, which must be drawn very tightly, and smoothly applied. This, covered with glue, forms the outside of the brace. It requires from twenty-four to forty-eight hours for this to dry, though much more quickly in the sun. It is then ready for removal, which is accomplished by cutting down in front and springing off the cast, with a small wad-cutter—or better, an ordinary belt-punch; this is perforated to any extent desired, care only being necessary to avoid the steel springs.

Leather strips, half an inch wide, with metal eyelets one inch apart, are sewed half an inch from edge in front, and laced with double lacing like a corset. This I have found to be the best way of securing the brace in front.

The brace is now lined neatly with canton flannel,

nap side out, or better material can be used if desired, linen answering well in summer. This can be renewed whenever cleanliness requires. It is well to let the lining extend an inch or more beyond the middle on one side, so as to form a tongue behind the lacing. The brace is now complete, as shown in Fig. 1. It

FIG. 1.

should be worn over a thin, tightly-fitting knit shirt, and is applied by springing open enough to admit the patient's body. The application of the brace to lateral curvature is somewhat different. The patient is first completely suspended, according to the method so fully described by Dr. Sayre; the object being to overcome the deformity as much as possible before applying the primary jacket. From this the solid cast is obtained, as above described. This represents the best possible position which the body can be made to assume. The wearing of a paper-jacket made over this cast would have the effect merely of retaining the advantageous position secured by the suspension, like the use of the plaster-jacket for a similar purpose; but would be of no avail in overcoming the deformity which still remained. This last can only be effected by some force acting continually upon the convexity of the thorax in such a manner as still further to straighten the spine. The power made use of in this case is produced by a band of sheet rubber (such as is used in making Martin's bandage), six inches square, which is sewed to the brace in front and behind, as shown in Fig. 2. So that when the brace is applied to the body, this band stretches tightly over the convex side of the thorax. In order that this force shall not be resisted by the opposite wall of the brace, a space must be left between the body and brace on the side of the concavity. This is secured by a slight alteration in the solid cast by filling out with plaster the depressions on this side, so as to make the contour of the cast regular. The amount of force can be regulated by varying the length and grade of rubber used. With these modifications, the brace for lateral curvature is constructed and applied precisely as in Pott's disease, previously described.

The chief points which recommend this brace to general use are the following:

1. All the advantages claimed for this plaster are secured without the objectionable features of:

1. *Weight and Bulk.*—The paper brace weighs from 8 to 16 ounces, the plaster-jacket from 3 to 6 pounds.

FIG. 2.

The plaster is from one-quarter to three-quarters of an inch thick; the paper rarely more than one-eighth of an inch, besides being an accurate model of the body. A dress can be fitted over it as smoothly as over an ordinary corset; a great advantage in the eyes of the mother, however much a doctor might ignore it.

2. *Imperviousness.*—Without stopping to discuss the question whether the plaster absorbs bodily moisture or allows it to pass through, it is certainly greatly inadequate to the needs of the body. The paper brace as first made without perforation was open to the same criticism. As now made, ventilation can be secured without loss of strength.

3. *Friability.*—A plaster-jacket will ordinarily last only four to six weeks before it begins to crumble, and is no longer efficient as a support. A well-made paper brace will last six months. In two instances, patients of mine wore braces eight months, when they were removed because the patients were well, the braces being still in good condition.

4. *The difficulty of securing a perfect fit.*—It is next to impossible to prevent irregularities on the inner surface of the plaster, because it is applied to the soft parts which are yielding. Two or three removals and reapplications are often necessary before one which the patient can wear is obtained. The paper jacket is made over a model which is at the same time firm and smooth, its inner surface consequently must be perfect. The same cast can be used repeatedly until the patient outgrows the brace.

5. *Difficulty of constructing a plaster-jacket which can be removed and reapplied at will.*—The paper brace can be taken off and adjusted as easily as a steel support, so that it is hardly possible for excoriations or abscesses to form without the surgeon's knowledge. Yet when it is applied and laced it secures as perfect fixation and rest for the parts as is obtained by the plaster. It also admits perfect cleanliness, the impossibility of which in the plaster is perhaps the strongest objection to its use.

II. The value of the brace lies in its adaptability to the need of the general practitioner in any part of the country. All the materials required are readily obtained; these are, plaster-of-Paris, materials for glue, paper, steel springs, bandages, and cotton flannel. The brace, complete, can be made and well finished for one dollar and twenty-five cents (\$1.25) or even less, the expense depending entirely on the amount of

finish. With a little experience the whole brace, excepting the time required for drying, can be made in an hour and a half.

III. The paper brace is believed to meet the indications in lateral curvature by a dressing more simple and efficient than any yet proposed.

In conclusion, I would say that the brace has now come into general use in Louisville and vicinity; the results obtained with it being such that, in the practice of the leading surgeons, it has almost entirely superseded the plaster.

Through the kindness of Dr. Knight I have, during the last few weeks, applied it to a number of cases at the Hospital for Ruptured and Crippled, and I hope soon to be able to establish, by statistics, the value of the brace. It is still open to many improvements, which further experience in its use will doubtless suggest. The desire to perfect it as far as possible has been my reason for not presenting it to the profession before.

135 E. 42D STREET.

A NEW FEEDING-BOTTLE FOR PREMATURE, FEEBLE, OR INVALID INFANTS.

By A. JACOBI, M.D.

[From Vol. I. of Wm. Wood & Co.'s forthcoming Treatise on Hygiene and Public Health.]

DAILY experience shows that new-born babies find little or no difficulty in sucking. Those who are not able to nurse will owe this incapacity to either muscular debility or to some other anomaly. Muscular debility may depend upon premature birth, or result from sickness and insufficient convalescence.

Another cause of inability to nurse may exist in dyspnoea, from either insufficient expansion of the pulmonary tissue, or from congenital or acquired disease of the lungs, or from heart disease.

Inability to nurse may also depend upon malformations. Not so much upon simple, uncomplicated hare-lip as upon double hare-lip, complicated with fissure of the palate. It very rarely depends upon anchyloglosson, now and then upon hypertrophy of the tongue, or upon ranula. In rare cases it also depends upon pseudoplasms of the tongue. I have myself described a case of congenital sarcoma of the tongue in the American Journal of Obstetrics, etc., August, 1869.

Nursing may also be interfered with by either simple or syphilitic nasal catarrh, giving rise to an accumulation of mucus, or blood, or mere thickening of the mucous membrane. Also by different forms of stomatitis—not only the thrush of the new-born and very young infant, but also by the erythematous and follicular stomatitis of the infant of more advanced age. To relieve children suffering from this difficulty of sucking, a nursing-bottle has been invented in France, and brought into the market under the name of "Biberon Pompe." I first gave publicity to this instrument on page 413 of the first volume of Gerhardt's *Handbuch der Kinderkrankheiten*, 1877, where I reported that a specimen of the apparatus in my possession was presented to me by Dr. O. Soltmann, of Breslau. Since that time Dr. Soltmann has modified the instrument to a certain extent, and published an account of it in an article entitled "On the Nutrition of Sick Nurslings by Means of a New Nursing-Bottle," *Jahrbücher für Kinderkrankheiten*, etc., Vol. XII., 1878, p. 406. The accompanying woodcut shows that a glass tube inside the bottle carries a small soft-rubber funnel, which is changed into a valve by

means of an oblique cut through one-half of its body. Simple pressure upon the mouthpiece, either by the lips or by the alveolar processes, or by the fingers, is sufficient to cause the liquid to escape from the bottle. In cases in which the baby is not able to exert even this pressure, the slightest pressure upon the bulbous expansion of the tube, seen in the woodcut, on the part of the attendant, is sufficient to propel the liquid food into the mouth of the child. The apparatus is

A, air-hole; B, mouth-piece; C, expanded part of sucking-tube D, funnel-valve.

to be recommended in just such cases as enumerated above, not only upon theoretical reasons, but from results derived from actual trial. About a year and a half ago, when I first exhibited the instrument before the New York Obstetrical Society, I had occasion to direct the management of a prematurely-born child with insufficient muscular development; and the infant was fed for months from this bottle, and thrived well.

In a case of spinal meningitis, occurring in an infant, and rendering it unable to suck, this bottle was used successfully; and the same can be said with reference to a serious case of follicular stomatitis, in which nursing was an impossibility.

The feeding-bottle can be obtained of Reynders, cor. Fourth Ave. and Twenty-third St., of this city.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from June 8 to June 14, 1879.

MCKEE, J. C., Major and Surgeon Medical Director, Dept. of Arizona, after inspection of post hospital at Fort Yuma, granted leave of absence for one month on surgeon's certificate of disability, with permission to go beyond limits of the dept. S. O., 64, Dept. of Arizona, May 31, 1879.

BIART, V., 1st Lieut. and Asst. Surgeon. The sick leave granted him from Hdqrs. Dept. of the Missouri extended one month on surgeon's certificate of disability, with permission to leave the Dept. of the Missouri. S. O., 137, A. G. O., June 11, 1879.

COLUMBUS MEDICAL COLLEGE.—Dr. D. Tod Gilliam, of Columbus, O., writes the reason why the Columbus Medical College became dismembered, and maintains that the statement made in the May number of the *Ohio Medical Recorder* has no foundation on fact. We hope no permanent damage will be done to either party, although it may be that both have unintentionally injured each other's feelings. "A soft answer turns away wrath, and grievous words stir up anger."

MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK.—Dr. James L. Little, formerly of the College of Physicians and Surgeons in this city, also Professor of Surgery in the University of Vermont, has been appointed Clinical Professor of Surgery, *vice* Dr. Joseph W. Howe, resigned.

NEW YORK SUPREME COURT.—Decision of Justice Lawrence in the case of Mary Ann Proctor against the Manhattan Eye and Ear Hospital, May, 1879.

LAWRENCE, J.—It appears that the defendants were organized under an act of the Legislature as a corporation, in the year 1869, and the object of the corporation is declared, in the second section of the act, to be the establishment of a hospital in the City and County of New York, for the treatment of indigent persons suffering from diseases of the eye and ear. The fourth section of that act provides that the Board of Directors shall have power to enact by-laws and regulations for the conduct of its officers and not inconsistent with the constitution and laws of this state. This is the language of the statute:

"Fourth.—No alteration or amendment of the by-laws, nor any addition thereto, shall be made except by a vote of a majority of the Board of Directors. The Board shall be convened for such special purpose by a notice to each Director, expressing the proposed alteration or amendment or addition, and the yeas and nays shall be taken and recorded in the book of minutes on each question, and shall elect by ballot, in case of vacancy, surgeons of the hospital, and appoint such other surgeons, agents, and servants, as they may deem necessary to transact the business of the said corporation, and designate their duties.

"Fifth.—The Board of Directors shall determine the qualifications for membership of the said corporation, and persons duly qualified shall be eligible for Directors in case of vacancies occurring in the Board.

"Sixth.—The corporation shall possess the general powers, and be subject to the general restrictions and liabilities prescribed in the third title of the eighteenth chapter of the first part of the Revised Statutes."

Under those provisions of the Revised Statutes, if my recollection is correct, the corporation is made subject to the visitatorial power of the State, which may be put in motion by the Attorney-General or other appropriate officers. After as careful and deliberate a consideration as I have been able to give to this case, I am of the opinion that the effect of that act is to create a public corporation, or, if not absolutely a public corporation, a quasi-public corporation of a charitable nature, and I am, therefore, free to say that I cannot, after such consideration, distinguish this case from the case which has been referred to, the case of *James McDonald vs. The Massachusetts General Hospital*, 120th Mass., p. 421, in which the court sitting in bank, in an opinion delivered by the present Attorney-General of the United States, and apparently concurred in by each and every member of the court, distinctly holds:

"That a corporation, the object of which is to provide a general hospital for sick and insane persons, having no capital stock, nor provision for making dividends or profits, deriving its funds mainly from public and private charity, and holding them in trust for the object of sustaining the hospital, conducting its affairs for the purpose of administering to the comfort of the sick, without expectation or right on the part of those materially interested in the corporation to receive compensation for their own benefit, is a charitable institution.

"The fact that a corporation, established for the maintenance of a public hospital, by its rules requires of its patients payment for their board, according to their circumstances, and the accommodations they receive, and that the trustees of the hospital determine who are to be received, do not render it the less a public charity."

Each and every one of those features, it seems to me, exists in this case, and on the facts, as well as upon the law, I again say I am unable to distinguish the case at bar from the case which I am citing. The court further held in that case, that a corporation established for the maintenance of a public hospital which has exercised due care in the selection of its agents, is not liable for injury to a patient, caused by their negligence, nor for the unauthorized assumption of one of the hospital attendants to act as a surgeon. Now, I do not think it can be contended for a single instant in this case that there is any proof whatever that the surgeons who attended the plaintiff, and who have been made the subject of criticism and complaint on this trial, were not

skilled in their profession. We have had before us the most eminent men in the medical and surgical profession in the city of New York, and their testimony has uniformly been to the effect that Dr. Loring, Dr. Ross, and Dr. Agnew were men who were not only highly skilled in their profession, but most pre-eminently so. There is no proof to the contrary on the other side; not a single medical witness, or surgical witness has been produced who has ventured to say that this operation was not a proper one, and was not properly performed. The only witness who has—I will not say assumed to criticize the operation—but who has spoken of the operation, was the husband of the plaintiff, who stated that he saw a watery substance run down the cheek of the plaintiff at the time the operation was performed. Of course, the evidence of a layman, as opposed to the evidence of all these professional men is no evidence whatever to go to a jury, and I find it my imperative duty, therefore, having determined that this is a public charitable or a quasi-public charitable corporation, to hold that it has complied with all the duties which the Supreme Court of the State of Massachusetts, when a similar case was presented to them, determined that a corporation should perform and exercise. Indeed, I regard the case before the Massachusetts Supreme Court as much stronger against the defendant in that case than this case is against the defendant here. There, "The plaintiff on December 9, 1870, fell from a building on which he was at work and his thigh-bone was fractured, and on the same day he was brought to the hospital of the defendant, and there remained in one of the wards until February 4, 1871, when he went away. While in the hospital he had gratuitously the surgical and medical care, attendance, and nursing which the hospital affords to its patients; he occupied a free bed, and all the expense of his medical and surgical treatment and nursing, and of his shelter, warmth, food, washing and bedding, were borne as a charity by the defendant. The house pupil, appointed as provided in the by-laws, and who in the first place set his fractured thigh-bone, and continued while the plaintiff was in the hospital to attend to the plaintiff's case under the direction of the attending surgeon, was a member of the Harvard Medical School, in the last three years of his professional study, and received his degree of M.D. from Harvard College in the following June, 1871; the attending physicians and surgeons recommended him for his post, and the visiting surgeon, who had direct charge of the treatment of the fractured bone, and under whose direction and supervision the house pupil acted in his treatment of the plaintiff's fracture, was a man of the highest professional reputation and skill; the said house pupil and attending surgeon treated the plaintiff's case gratuitously, and according to the regulations of the Massachusetts General Hospital.

"The treatment of all cases in the hospital is by the visiting physicians and surgeons, and the house pupils acting under their direction, each officer having the exclusive care and control of all patients assigned to them, and such physicians and surgeons acting gratuitously, the defendant providing for patients without means, like the plaintiff, the hospital nurses, bed, food, warmth, and other comforts gratuitously; such visiting physicians and surgeons are practitioners in the city of Boston, outside of the hospital, and are selected by the trustees of the hospital to treat gratuitously patients who come to the hospital for gratuitous treatment; and this was the relation of the visiting surgeon to the defendant in this case.

"The plaintiff offered to prove that on the day he came to the hospital he objected to the house pupil having anything to do with his fractured leg, and that he wanted, and asked to be permitted to wait till the return of the resident physician, who was at the time absent. The plaintiff also offered evidence that previously to this time it had frequently happened that when a patient was brought in having been injured by accident, the house pupils received him and treated the case, if they so desired, without consulting any resident or visiting physician. The plaintiff offered other evidence which he claimed tended to show that the fractured bone was not properly set by reason either of the incompetency and negligence of the house pupil or of the negligence of the attending surgeon.

"The judge ruled that even if the plaintiff should prove that the fractured bone was not properly set in consequence of the incompetency of the house pupil, or the negligence of the house or the attending surgeon, the plaintiff was not entitled to recover, and the jury rendered a verdict for the defendant." This was excepted, and it came before the court in bank. I do not propose to go over the opinion, as I have stated the conclusions arrived at by reading the syllabus of the case, but I do wish to refer for a single moment to one paragraph of the opinion of Judge Devereaux. "It might well be questioned whether any contract could be inferred between the plaintiff and the defendant. It has afforded to him freely those ministrations which, as the dispenser of a public charity, it has been able to provide for his comfort, and he has accepted them. It has no funds which can be charged with any judgment which he might recover, except those which are held subject to the trust of maintaining the hospital. If, however, any contract can be inferred from the relation of the parties it can be only a contract in the part of the corporation that it shall use due and reasonable care in the selection of its agents." And then he goes on to hold that that due and reasonable care in the selection of agents was shown in that case, and I hold, as matter of law, that upon the uncontradicted evidence in this case due care and due skill have been shown to have been exercised and exercised by this corporation in the selection of the visiting surgeons who operated upon, or who were consulted about the operation which was performed upon the plaintiff's eyes.

I might well rest a dismissal of this complaint, I think, upon the point which I have just stated, but I prefer to notice another. The burden of proof in this case, as in every other, is upon the plaintiff, and the plaintiff, before he can call upon the court to send this, or any other case to jury, must make out in law a *prima facie* case. In the case of *Carpenter vs. Burke*, the Supreme Court in the Fourth Department of this State held that, "One who offers himself for employment in a professional capacity undertakes:

"First.—That he possesses that reasonable degree of learning and skill which is ordinarily possessed by the professors of the same art or science, and which is ordinarily regarded by the community and by

those conversant with the employment as necessary to qualify him to engage in such business.

"*Second*.—That he will use reasonable and ordinary care and diligence in the exercise of his skill and the application of his knowledge to accomplish the purpose for which he is employed.

"*Third*.—That he will use his best judgment in the exertion of his skill and the application of his diligence."

As I have said on the other branch of the case, the proof is overwhelming and uncontradicted, that in this case the surgeons consulted and employed, exercised reasonable and ordinary care and diligence in the exertion of their skill, and if they did make a mistake in judgment I would not be justified in sending this case to the jury.

In this case the proof is also overwhelming and uncontradicted that the best judgment of these physicians was exercised. There is no proof on the other hand. Not a single medical witness or surgical witness has been produced on the part of the plaintiff who has assumed to say that this operation for glaucoma, which was determined by the examining physicians to exist, was not a perfectly proper and reasonable operation, and one which duty required them to make and, therefore, I can very safely rest this case upon this point that the plaintiff has not made out a *prima facie* case to go to the jury, even if this were a case which had been brought directly against the surgeons or the physicians for malpractice. There have been during the course of this trial, some allusions to the great hardship of the case. We all recognize that, and no one can see the affliction under which the plaintiff labors without extending to her his sympathy and his condolence, but with those considerations I cannot deal. It is my duty to enforce the law as it has been laid down and expounded by the judicial tribunals who are my superiors, and however unpleasant the duty may be I hope I shall never be found unable to discharge and perform it. For the reasons stated this complaint must be dismissed.

PROVISIONAL REPORT OF THE COMMITTEE OF THE NEW YORK NEUROLOGICAL SOCIETY, RELATIVE TO THE SUBJECT OF INSANE ASYLUM ABUSES, ACCEPTED BY THE SOCIETY JUNE 2D.—The undersigned, constituting the Committee on Insane Asylum Abuses of the New York Neurological Society, respectfully report that the petition prepared by them, and which contained the complaints deemed most important, was signed by many prominent physicians, lawyers, and other citizens, and presented to the State Senate on the 20th of March last.

It was referred by that body to two members—Mr. Goebel, of this city, and Mr. Goodwin, of Utica—constituting the Committee on Public Health. That committee has now made a report so unfair, one-sided, and so grossly misrepresenting the real facts of the case, that we feel called upon to solemnly protest against its being received by the profession and public as even remotely embodying the results of a *bona fide* examination. There was not even the pretence of a fair examination made, documentary evidence was excluded, the bias of the Committee was evident from the first, and they were surrounded by superintendents who had been examined the day previous, without any member of your Committee being notified thereof.

One member of your Committee who was examined at Albany, was forced, in self-protection, to protest against the passing, from superintendents to the Senator examining, of slips of paper containing questions desired by the former to be propounded to the witness, and superintendents were repeatedly seen to prompt that Senator. It may suffice, in possible explanation of the bias of the Senate Committee, to refer to the fact that the Senator conducting the examination is a resident of Utica, and strongly affiliated with the authorities of the asylum there located. It will be noticed that the Senate Committee is extremely careful in summing up its so-called conclusions, to speak of State institutions exclusively (meaning asylums supported and controlled by the State alone), although the petition distinctly referred to all lunatic asylums within the State limits.

As further characterizing the animus of the Senate Committee, we may refer to the fact that their piece of special pleading, miscalled a report, has been extensively circulated among superintendents and their friends, although no member of your Committee has received a copy, and we have no other knowledge

of this report than that furnished by the daily papers.

It is also worthy of note that the Senate Committee, although informed that much valuable evidence could be obtained in New York, where most of the petitioners resided, evidence which could not be obtained at Albany, avoided receiving this testimony by refusing to meet anywhere but in Albany.

Your Committee has been charged by the partisans of the asylum interest with having appended names to the petition without authority, and misrepresenting its purport to signers. These charges are false in every particular; every name appended to the petition is authentic, and no one signed it without having had full opportunity to read it and become acquainted with its intent and purposes. It is true that a few of the signers became alarmed when they received a *quasi* threatening summons from the Senate Committee, and wrote that they withdrew their names, and that still a few others withdrew theirs at the personal solicitation of the superintendents, but the greater number of signers, including many prominent physicians, continue to affirm the pertinency of all the inquiries, and the necessity of a full investigation.

Your Committee proposes within a reasonable period to present a detailed report, exhibiting the actual character of the testimony presented, as well as other evidence which was excluded, in support of the allegations set forth in the petition. Your Committee is conscious of the fact that they require no better indications of their position.

The Committee.

SPASMODIC DISORDERS OF THE LEGS.

PHILADELPHIA INFIRMARY FOR NERVOUS DISEASES.

S. WEIR MITCHELL, M.D.

(Prepared for THE MEDICAL RECORD.)

GENTLEMEN:—I have frequently called attention in this clinic to cases of spasmodic spinal paralysis, and have also not neglected to point out the fact, which Dr. Seguin and others have also long ago mentioned, that spasms of the legs and a prolonged rigidity are to be found in numerous and widely different cases of spinal disease.

My own clinical experience would lead me, as regards this matter, to the following conclusions:

1. That there are many forms of spinal trouble, myelitis, tumors, syphilitic alterations, etc., in which we find these symptoms as incidents in the course of the disease.

2. That there are rare cases in which spasms of the legs are due to obscure functional conditions, and in which these symptoms seem to be temporary, and to constitute the sole objective symptoms.

3. That the group of symptoms described by Seguin as tetanoid paraplegia, and by Erb and Charcot as spasmodic spinal paralysis, or spasmodic dorsal tabes, constitutes a distinct disorder, probably due to sclerosis of the lateral columns of the cord.

There have not as yet been so many cases of spasmodic spinal palsy reported as to deprive of interest thorough statements of other cases; so that the facts I shall add concerning these will not lack value. Moreover, in the matter of functional disorders of the lower limbs with spasm, I shall have quite enough to say of what is new, to justify me in calling your attention to this part of the subject.

I am not as yet quite sure that we may not be justified in making a distinction between two classes: perhaps they are species, or, haply, but varieties of spastic spinal palsies. This distinction would lie in the fact that we have one set of rare cases in which the spastic element is purely a rigidity, without large tremor or spasm—a rigidity caused by every muscular movement, active or passive.

The other set of cases presents like states, with excessive spasms of the legs on slight irritation; so that the rigidity which motion causes is accompanied with intermittent spastic phenomena and more or less paralysis.

Examples of the first group are rare; but when they occur with some paralysis, slight vesical troubles, and absence of sensory disturbance, I am disposed to refer the case, without much doubt, to the Erb-Charcot group (lateral sclerosis). In proportion, however, as the case exhibits, with these symptoms, differences, together with *excessive* phenomena in the way of temporary clonic spasms (Séguard's spinal epilepsy), am I disposed to suspect the presence of some cause other than mere sclerosis. The distinction may not be entirely just; nor, of course, do I wish to deny that trepidation makes part of many cases of lateral sclerosis; but, at the same time, I wish to point out that I have now seen several cases in which, with every other symptom, there never was either permanent contracture or any form of large tremor. These were instances of more or less loss of power in the legs; of nearly undisturbed sensation;

of slight or negative vesical symptoms; of varying rigidity of the limbs.

Without giving these cases at length—and I saw both through many years, and until they died—I will relate their history in a condensed form.

Mr. L., a clergyman, of almost ascetic habits, began at the age of forty, and without known cause, to feel feeble. The weakness was worst on rising in the morning, and faded away before ten A.M. By and by, within a year from the first symptom, he began to have a singular walk, and then first applied to me; at this time he was, he said, less weak than he had been, and believed that the stiffness of the limbs, while it annoyed him, enabled him to stand, and even to move, with less effort. I ceased to reflect on this statement, until it was repeated in connection with another case quite recently. As I shall point out, it has its interest. In Mr. L.'s case the lower limbs were strangely rigid, and the stiffness was so nearly balanced, as regards the opponent muscles, that he walked chiefly by throwing forward first one and then the other side of the pelvis, so as thus to carry the feet forward in turn. At the same time the spine itself was somewhat stiff, and the head carried well back. To get on to his feet was a vast exertion; but once erect, he contrived to move in the singular style I have just described. To sit down, he would seize a chair-back with one hand, and then let his rigid legs slip forward, so that he fell on to the seat. Once seated, he managed, with one hand, to get hold of the pantaloons at the back of the calf, and, while he drew this towards him, with the other hand he held the thigh firmly. By these manœuvres he contrived to bend each leg. Once bent, they remained so until, by a desperate and often unsuccessful effort of will, they were again put into a state of extension. When at rest, as when seated, these limbs presented in perfection what we call here the "lead pipe" symptom—that is, to flex or to extend them was equally difficult; and the regularity and steadiness of resistance was precisely what is felt when we endeavor to bend a leaden pipe. If, when he was at rest, I lifted one leg a foot or two, and there left it, it would remain almost motionless for a moment, and would then descend by the aid of its own weight, without notable tremor. Every effort to move the legs, whether by act of will or passively, met with steady resistance, which, if overcome by abrupt violence, gave rise to pain. If he tried, by act of will, to prevent the raised limb from falling, the descent became, as it were, broken into a series of partial falls, with intervals of slower descent. With this remarkable condition, Mr. L. had no bladder trouble, except after six years some slight paresis; neither had he ever any sensory disturbances. His death was probably due to a cerebral hemorrhage, and took place when he had suffered about ten years from the spinal malady. As the case was interesting, and might have proved valuable, I was of course denied the privilege of a post-mortem section.

I recall most distinctly a very similar case, in which I was for only a few months the attendant.

This gentleman, at about forty-four when attacked, had been an excessively overworked professional man. He had never had syphilis. His trouble came on with vague discomfort in the back—a tired ache. Within a year or two the rigidity of the calves began to show itself, and by degrees this extended to other muscles until it became almost universal.

The arms and legs and back, and even the neck, were affected, and, late in the case, the patient insisted that the facial muscles were also somewhat

stiff. The rigidity was extreme, and the source of great discomfort, which was relieved, although only for a few minutes, by free passive movements. I believe the bladder was never seriously affected; and, except for some sense of numbness, there were no symptoms connected with touch.

The following history of a case of spastic paralysis corresponds closely to Charcot's description; but the clonic spasms were never very remarkable:

P. C., single, *æt.* 32; born in New Jersey. The patient's family history is good, and, as far as it can be obtained, is free from hereditary taint. When a child, she was considered remarkably healthy. At the age of ten years she had scarlatina; but from this she made a perfect recovery.

She has never had intermittent or typhoid fever. Her menstrual function began at the age of fourteen; and since then it has been performed regularly, and in a perfectly normal manner.

In February, 1878, while feeling perfectly well, she caught her foot, and fell heavily upon her left side, bruising her thigh, but not striking her head or spine. She recovered very soon, and does not consider that the injury had anything to do with the onset of her present trouble, for which she can assign no cause whatever. She has led a very easy life, and has always been very careful about exposing herself to cold and damp.

In June, 1878, she began to notice a slight degree of numbness in her legs between the knees and ankles, both legs being similarly affected; and soon after this, she noticed that her toes dragged a little, and had a tendency to catch in anything projecting at all above the level of the floor; and when she walked with bare feet, the toes of the right foot would sometimes turn directly underneath the sole.

The muscles of the legs, soon after this, began to grow stiff, so that free motion became impaired. In walking, her feet fell very heavy, and would strike the floor heavily; her friends telling her she walked as if she had "cork legs." Going up and down stairs was particularly difficult. Sometimes in walking she noticed that, besides the difficulty of touching the ground with her heel, her ankles had a tendency to turn outward; and, to avoid this as much as possible, she laced her shoes tightly. She has never noticed any difficulty in walking in the dark, although the sensation of her soles was impaired.

This latter symptom made its appearance about August, and extended part way up her legs; although it was most marked in the soles of her feet, the carpet not feeling as distinct to her as it should.

About this time, in getting down from a car, she was obliged to jump, as she was unable to step down. She alighted heavily upon her feet, and jarred herself very much; and for two or three days she experienced considerable pain in the sacral and lower lumbar regions; with this exception, she has had no spontaneous pain whatever. She thinks the symptoms made a more rapid advance immediately after this accident than they had previously done.

In September she noticed, for the first time, slight spasmodic twitches in her legs, particularly when quiet in bed; and these have continued since, becoming slightly more severe.

One month ago (latter part of September), owing to the gradual increase of the muscular rigidity, she was obliged to have help in order to get about. The abnormal sensation in her legs by this time had extended half-way up her thighs; but within the last two weeks it has extended to her body.

Two weeks ago she discovered a small spot at the

junction of the lumbar and sacral vertebrae, which was quite sensitive upon pressure with the point of the finger, but not with a larger surface.

Within the last week slight difficulty in urination has made its appearance; the trouble being to evacuate her bladder even after she feels a strong desire to do so. She is naturally slightly constipated; but this symptom has increased lately also. Coldness of the feet has been a marked symptom, and even brisk friction would fail to warm them or to remove their pallor. She has never had the least sensation of a girdle; nor has she ever had any pain in the extremities.

Her arms appear to be entirely free from trouble; and the tactile sensibility and power of movement is perfect.

When standing in bare feet, the left ankle bends outward; and, although she can lift the left leg from the floor, she is utterly unable to move the right foot; nor can she stand without support.

Sitting up is a little difficult, on account of the rigidity of the muscles about the hip; and, when in this position, she finds it much easier to extend than to flex her legs. The power of the extensors is good, patient being able to resist flexion very strongly, while she cannot resist extension of the legs with nearly as much force.

The legs, when first moved, are somewhat rigid, and have a tendency to remain in the position in which they are placed; but after a little manipulation this disappears to a great degree. The adductor muscles of the thighs are likewise rigid, and the legs cannot be widely separated.

A very light tap upon the patella tendon of either leg causes a violent contraction of the extensor muscles of the thigh, and forced flexion of the foot likewise causes a spasm of the leg. This is particularly true of the right, although this procedure does not always cause the spasm. The slightest prick of a pin causes a very perceptible reflex spasm.

The compass-points cannot be recognized as two upon the soles of the feet, the points and the round end feeling about alike to the patient. Upon the dorsum of the left foot the points are recognized as two when two inches apart, and on the right foot when one and three-fourth inches apart (the normal distance being a little over one inch.—A Flint, Jr.). Over the patella of the right leg the points are distinguished when two inches apart, but not on the left side (normal distance being nearly one inch). Upon the thigh the sensation is nearly normal.

No apparent atrophy has taken place in the legs, both calves measuring alike—*viz.*, eleven and a half inches. The reaction to induced current appears about normal, perhaps slightly increased. Pressure over upper sacral region, in the median line, or on both sides of it, causes considerable pain; and this region is quite sensitive to the galvanic current (negative pole), which causes but very slight sensation higher up. There is more sensitiveness to the current upon the right side than upon the left.

When lying in bed, her feet are strongly extended, and resist flexion quite powerfully. The feet are cold; there is no œdema. As before mentioned, there are occasional twitches in both legs.

Her appetite is fair; there is no cough; urine normal.

There is a considerable fibroid growth on the anterior aspect of the womb.

Dec. 7, 1878.—The legs have a tendency to remain flexed; and the feet are extended, owing to the contraction of the gastrocnemii group of muscles. The

other muscles are relaxed, so that the legs no longer show a tendency to remain in any position in which they may be placed. There is an increase of the wasting previously noted, the calves measuring a half inch less than at last measurement. She is utterly unable to stand without assistance, as her knees give way beneath her. The muscles of right leg contract more promptly to secondary interrupted current than do those of the left; and there is occasional spontaneous twitching of the extensors of both thighs; but this symptom is diminishing.

The reflex action of the tendons remains about the same as at last trial (*viz.*, increased). The feet feel cold to the hand, although to the patient there is a frequent sensation of burning in them. The capillary circulation appears about normal. The toe-nails grow equally and naturally.

Pricking the insteps with a pin produces a sensation of pain in leg from knee to ankle, but no sensation at the point touched; and she cannot tell when the soles of the feet are touched. Sensation is impaired upward as far as a line drawn around body on a level with the anterior superior spinous processes, and at this point it apparently ceases abruptly. The patient, however, has perfect control over the sphincters at present.

There is no pain on pressure over abdomen, although there is spontaneous pain in the right iliac region, which the patient can bring on by sneezing or coughing. This pain is not modified in any way during the menstrual periods, which recur with regularity, and are normally performed. The painful spot over the sacral region is still present, and is limited to an area one-half inch in diameter; it gives no trouble. The patient does not think that the tumor has increased lately in size at all.

At the time I speak, this case has become worse; but the sensory disturbances have lessened rather than grown.

While here under my care this woman's case enabled me to study with care some aspects of the symptom rigidity, to which I have already alluded.

When she arrived, and I understood how troublesome was this symptom, I directed, among other means, that a practised masseuse should treat the stiff legs an hour daily. The treatment was simply kneading, with as little irritation of the skin and as little motion of the legs as could be managed consistently with thorough massage of the muscles.

Each treatment was found to lessen the stiffness, and in a few days it disappeared, to my great pleasure and that of the patient. Our happiness was short-lived; for when she tried to walk or stand, it was found that she fell at once, unless sustained, and was unable, as before the massage, to stand at all, or to move across the room. The cause was but too plain. The rigid limbs acted as splints, and enabled her, with the slight aid of her enfeebled muscle-power, to stand or walk a few steps. Without the rigidity of limb, the supply of nerve-force was insufficient to effect these purposes at all. After two or three days without massage, the stiffness returned, and with it capacity to stand. I had, indeed, given her a more than dubious help; and the massage was of course an experiment; but I was surprised to find that the handling did not increase the spastic phenomena. It is to be remembered, however, that in this woman's case the tremor and clonic spasms were not very marked. I may now recall the statement of Mr. L., Case I., who began by being weak in the legs, and was for a time made to feel less feeble by the invasion of the rigidity, which, after a while, entirely destroyed all power to move.

The most extreme case of these disorders I can recall I saw but once many years ago in the person of a priest, who had become rigid—almost literally from head to foot—since the neck and back muscles were involved, and there were, as I remember it, even in this advanced stage, no contractions save in the left hand, and in the adductors of the thighs. I have no notes of this case which I call up from memory. There were some curious cerebral symptoms, not the usual ones, and it may have been an unusual case of disseminated sclerosis. I mention it to describe a singular fact. The man was totally unable to speak until some one raised either leg, and moved it freely. If this did not answer, an arm was also thus exercised, and at last after a few moments he would begin to speak and continue to do so easily enough—so long as he did not pause. A half minute of silence made it needful once more to move the limbs, in order to enable him to speak again.

This phenomenon, curious as it is, does not stand quite alone in my experience. I saw some years ago a typical case of spastic spinal paralysis, in which there never was at any time the least evidence of spasms from the skin reflexes. Although sensation was perfect, abrupt or slow motion, passive or active, caused rigidity of the opponent group, but the reaction was firm and steady, not jerky. A few passive motions made regularly seemed to lessen the resistance, and even for a time to wear it out. The patient himself remarked to me that these exercises also relaxed notably the corresponding limb, and this was, indeed, plainly apparent. The absence of tremor, when this man was put on his feet, was striking; for although the great stiffness made needful some aid to enable him to keep his balance, there was lacking almost altogether the quivering play of the tendons, so marked in many of these cases; neither was there ever, in a history of seven years cut short by tubercle, any permanent contraction of the fingers. The bladder was not troubled for at least three of these years, and was never more than feeble.

Rigidity, with or without clonic spasms, is to be found in many clinical groups of symptoms. Cases accurately filling the required role of Erb-Charcot symptoms without exceeding it are, as I have said, somewhat rare. The following case, which came to the clinic of my friend Dr. Sinkler, is an interesting illustration of rigidity, tremors, and various other symptoms which leave me in much doubt as to the pathology.

Charles Perry, *æt.* 36; married. Patient has worked in lead paints for twenty years or more, but he has never had colic or constipation, nor has a blue line ever been detected upon his gums. He denies venereal taint.

In the spring of 1875 he was attacked, without any particular cause, with pain in the right shoulder and elbow; the pain would start in the elbow, shoot up the arm to the shoulder, through the shoulder-blade and back again to the elbow; this pain was sudden, sharp, and quick in character, and continued about the same for two years. In 1877 he was obliged to give up all work on account of the pain and the weakness of the arm, as considerable wasting of all the muscles of the shoulder had set in.

When first seen at the hospital, in September, 1878, the patient complained of shooting pains in the shoulder-blade and in the head; his appetite was poor, and a meal was invariably followed by water-brash and headache; he had tinnitus aurium and slept but poorly. Often in attempting to speak there would apparently be a spasm, which would suddenly arrest the

speech; as he expressed it, "something caught him" in the throat.

While sitting upon a chair there was a slight rhythmic trembling of the right hand and arm; when walking, the shoulder and pectoral muscles would begin to tremble, and the tremor of hand and arm would become much larger and pendulum-like in character. Even when in a recumbent position this tremor would continue, so that in order to get to sleep he had to lie upon the arm. When standing, there appeared to be a tenseness and rigidity of all the muscles of the right side, which tenseness was much increased during walking, at which time the patient would be drawn a little toward the right side; the ribs on right side appeared drawn together as if the intercostal muscles were also affected.

The right foot dragged a little during walking, and the great and next two toes were drawn toward the sole; his right thumb was drawn into the palm with sufficient force to cut the skin with the nail; this flexion of thumb relaxed when patient was recumbent.

Eye ground.—O. S. deep physiological cup, pulsation of veins, cribriform fascia sharply defined, disc indistinct, relation of veins to arteries normal. O. D. cup deeper, otherwise the same.

Urine normal.

There was no difficulty of swallowing, but occasionally immediately after eating he would eject considerable thick mucus (oesophageal vomiting?).

R. Ol. morrhuae, f̄ss. s. d.; Elix. ferri, quin. et stryeh., f̄3 i. t. d.

Grip of both hands alike, registering by dynamometer 130. No dragging of right leg in walking, and April, 1879, a diminution of the tremor.

Improvement since October; patient stronger; less fibrillar tremor. Eructation of mucus still present; character of food taken immaterial as regards after-effects.

R. Half tumbler skimmed milk every one and a half hour during day, and nothing else.

Stop ol. morrhuae, etc.

Great improvement; tremor gone; likewise headache and eructation.

Has confined his diet to three quarts of milk daily. Worse again as regards tremor.

Has gained twenty pounds since October. Pain in loins, across back of neck and in ear.

Tendon reflexes; left leg about normal; right leg a little increased.

The symptom rigidity, in the form of general stiffness of the mass of muscles of the legs, increasing with all forms of movement, has an interest apart from the spinal malady, of which it seems to be one of the characteristic signs. I have seen it in children a small number of times associated with defective cerebral development. The rigidness was marked and the walk in two cases curious, since the posterior muscles being those most attacked, the poor little lads were nearly pulled over backward at each step. I have also seen cases of spasms of the adductors of the thighs; but, although I have had circumcision done in some cases where the phymosis seemed a possible cause, I have never as yet known the operation to do good. I do not doubt, however, that irritation of the sexual organs is sometimes a source of adductor spasms. There are rare cases of spasms of the legs which seem, as yet, inexplicable, because they do not permit us to ascribe them to any pathological change in cord or brain, but, passing away, leave the patient as free from annoyance as would a light attack of epilepsy. I have seen two such cases, and I have found nothing like them in any of the books.

A lad, æt. 17, thin, but of good color and fair health, was the orphan child of parents both of whom had died of pulmonary tubercle. After exposure to intense heat he was attacked with headache, and before this left him—that is, in forty-eight hours—he began to complain of dull aching in the legs. The next day he was somewhat stiff in moving, and on the day after was unable to walk. At this time I saw him. He had legs so rigid that it was difficult to bend any part of them. When bent it was as difficult to extend them again. Both of these passive movements caused some dull pain. There was hardly any tremor, and neither plantar irritations nor sudden movements caused irregular spasms. Sensation was absolutely perfect, the bladder in good order, the secretions normal, and there was no pain in the back. By slow degrees this remarkable rigidity disappeared, and the boy was well at the close of three weeks. I sought in vain for a cause for this attack. It was possible to exclude every usual source of irritation which might be called on to explain the rigidity as due to excitation of the spinal cord, nor was there the least reason to regard it as a neurosis of psychical origin.

Not less mysterious was the second case, that of Mr. L., æt. 43, a city official, large, sturdy, a full but somewhat regular liver, free from any taint, and of healthy ancestry. He was in his third attack when I saw him in the middle of the night. The previous attacks came on like this one, without warning; that is, he was well in the morning, and in the early afternoon began to suffer pain in the back and legs, with increasing stiffness. Before midnight the disorder was at its height, and had never lasted over thirty hours.

When seen by me the patient was seated in an easy-chair, which he preferred to a bed. He was flushed, sweating immensely, temperature nearly normal, pulse up to 135. The legs were extended and moderately stiff, but the least handling of them caused them to be thrown into intense spasms, during which the belly muscles also contracted, and the legs and feet were extended violently at brief intervals and with agonizing pain, which, as he described it, passed through the whole of the muscular masses of both legs, and between the spasms left him with a dull, aching pain. It was difficult to resist the idea that the man was poisoned with strychnia, but, above the waist, every motion was as usual, while the lower half of the body was in a state of severe tetanus. Under free use of narcotics these strange symptoms were readily relieved, and within sixteen hours entirely disappeared. The cause is to this day as much a mystery as it was at the time I saw him.

I have said nothing here as yet about the treatment of spastic spinal palsy, but I am inclined to state that I have seen more cases of spastic spinal palsy, and of amyotrophic lateral sclerosis which were to a degree amenable to treatment, than I have of posterior scleroses. Perhaps if the symptoms related themselves as definitely to the pathology in the former disease as in the latter disease, I might change my opinion. I do not expect to cure any case of distinctly pronounced sclerosis, but there are ways of helping, and at least of relieving, many of these distressing cases. This is especially the case where the sufferers are poor and have been ill-fed and forced to labor. Then the change to quiet and rest, and the comfort of good rooms, the wholesome, abundant food and tonics, often make an improvement which, however, but too soon reaches its limit. What we have done has been not to lessen the disease, but to improve the rest of the

economy. If a man can throw on to his muscles only a small part of the usual will-force, to improve his tone is to give his centres a greater capacity for evolving power, and his muscles a larger capacity to respond.

In painful cases of spastic paralysis I have found it most comforting to use hypodermic injections of morphia, nor should I fear their use, but would, in pronounced cases of this terrible malady, be quite willing that my patient should form a morphia habit. I have also employed atropia with morphia and alone, and also gelsemium; but although it is possible, with help of the latter drug, to lessen the spasms, this can only be done by doses such as give rise to vertigo; very large doses of bromides may also lessen the spasms. The permanent rigidity is of course distressing, but in some cases it is only the violent clonic spasms which give rise to pain.

Original Communications.

CAUSES OF DEATH IN SURGICAL OPERATIONS.

By A. L. RANNEY, M.D.,

ADJUNCT PROFESSOR OF ANATOMY, MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK.

PART I.

It is my desire in this paper to direct attention to those causes of death which occur during surgical operations, and to study those measures on the part of the surgeon which will tend to modify their severity, or, by preventing their occurrence, decrease the danger to life.

I shall divide these causes of death into: first, those dependent on the *blood-vessels*; second, those dependent on the *nervous system*; and, third, those dependent on the *blood*.

I shall consider, under the first, causes dependent on vessels: 1st. Hemorrhage; 2d. Air in the veins; 3d. Apoplexy; 4th. Embolism.

Under the second, causes dependent on nervous system: 1st. Shock; 2d. Collapse.

Under the third, causes dependent on blood: Anæsthetics.

I proceed first to the discussion of hemorrhage, as the most frequent cause of death during surgical operations.

HEMORRHAGE.

To die of repeated hemorrhages, while perhaps the most painless of deaths, is the most awful. With each succeeding hemorrhage, dissolution is so distinctly intimated, and the patient is so conscious that his strength is fast ebbing, that he clings to life. The most resolute are overcome with an anxiety which they cannot conceal, and look around for some one to delay, at least, the fatal moment.

But if there be a sudden hemorrhage from a vessel opened in an operation, or from an aneurism, or from some wound, the arteries of which cannot be discovered, there is immediate danger of death to the patient, even while in the hands of the surgeon. Those who have witnessed the agitation of such scenes can best judge of the importance of this subject.

John Bell, in his essay on hemorrhage, though undoubtedly influenced by the defective means of arrest then existing, closes a paragraph with these words: "Were this one danger removed, would not

the young surgeon go forward in his profession almost without fear?"

I question if even our present enlightenment has entirely dispersed this element of anxiety.

Hemorrhage is usually classed into three distinct varieties: 1st. *Arterial*, as indicated by a bright red color of the blood and an intermitting flow; 2d. *Venous*, as indicated by a continued flow and darker color; 3d. *Parachymatous*, as indicated by a general oozing from the capillaries of injured surface.

CAUSES PRIMARILY MODIFYING HEMORRHAGE.

The amount of hemorrhage is *modified* at first by the number of vessels wounded and by the smoothness of the cut surface.

This latter element is especially important in vessels of large calibre, since an injury with a dull instrument, or the rending of a vessel from violence, leaves the mouth in a condition to offer more or less resistance in itself to the rapid escape of blood, independent of the changes which occur in the coats of the wounded vessel subsequent to its injury.

CAUSES TENDING TO PROLONG HEMORRHAGE.

There are, however, other causes which may modify hemorrhage *later on*, and, by *prolonging* it, tend to greatly increase the danger to life. Under this head I would mention:

1st. *Gravity*.

2d. *High temperature*, whether in the wound or surrounding atmosphere, by delaying coagulation.

3d. *Muscular expiratory efforts*, especially in wounds of the neck.

4th. *Obstruction to a free venous return*.

5th. *Obstructed or delayed contraction of vessels*, as occurring in hepatic hemorrhage; from the teeth; from the nutrient artery of bone; from disease of the vessel; and from atony of vessel.

6th. *Diseases of blood*, preventing coagulation or assisting exudation, as in *vicarious hemorrhage*.

7th. *Congenital anatomical defects* in the construction of vessels. Wilson's case: *Lancet*, 1840; coats only one-half normal thickness. Blagden's case: *Med. Chir. Trans.*, vol. viii., p. 224; transparent coats—died from pulling tooth. Trachsmuth's case—death from ruptured hymen.

PATHOLOGICAL CHANGES DEPENDENT ON HEMORRHAGE.

These changes may properly be grouped under three heads:

1st. Changes in the constituents of the blood.

2d. Changes in the heart's action.

3d. Changes effected in the tissues.

There has been much discussion whether changes in the blood constituents, dependent on injury to tissues, and vessels, are always uniform. I think that in those forms of violence causing marked injury to tissues, that all the steps of an inflammatory process must necessarily occur within the injured tissues, and that the customary blood-changes in inflammatory blood must also *coexist*, provided that sufficient *irritation* has been produced to cause constitutional as well as local symptoms.

But I am by no means certain that in those cases of injury to a vessel, where the tissues are but *slightly* involved and the hemorrhage small in quantity (thus causing little, if any, direct constitutional effect), a markedly altered *blood-condition* is developed, or that increase of the fibrin and albumen could well be verified.

I am inclined to regard "blood-changes," dependent on injury to vessels and tissues, as but a slight

factor in the reparative process which nature sets up unaided; and also to think that the "increased plasticity" of the blood, so much discussed as aiding nature's arrest of hemorrhage, is not only dependent on the amount of irritation produced by the injury on the tissues, but in many cases may be wholly absent.

Not so, however, with those changes in the blood localized within the wound, and dependent, not on chemical alteration in its constituents, but rather on mechanical obstruction in the vessel, from the increased density of its fluid, resulting from a sluggish current and constant exudation of the plasma.

I do not feel that a lengthy description of the changes in the vessels following an irritant is admissible; but we have, doubtless, all perceived how in the web of a frog's foot, under the glass, are seen, successively, the stage of capillary contraction, of capillary dilatation, resulting in active hyperæmia, and followed subsequently by congestion, stasis, swelling of tissues from exudation of plasma elements, and transudation of white corpuscles.

We know, also, that the red blood-corpuscles, when deprived of the normal amount of plasma by exudation, show an apparent increase of adhesiveness and a tendency to pack themselves together like coin in bundles.

This adhesiveness seems to me, however, a purely local condition and a mechanical result of the escape of the plasma, not attributable to a general blood change or necessarily a *prima facie* evidence of general increase in the fibrin.

We may state then, in summary, without going too deeply into argument, that the changes in the blood, dependent on injury to vessels, are of a local and constitutional character; that the local conditions are mechanical in their causation, and, therefore, more or less uniform. While the constitutional conditions are dependent on some changes, resulting from irritation at the seat of injury, and are variable, not only in their degree, but even in their actual existence.

We pass to the second set of changes, due to injury of the vessel, viz., "changes occurring in the heart."

II. *Changes in the Heart.*—Immediately upon the opening of a vessel of large calibre constitutional effects appear in direct proportion to the amount of blood lost. These effects are mostly confined to the heart and general circulation. The heart gradually loses its normal power, and becomes accelerated in its action. The arterial tension in the superficial vessels shows rapid diminution, and the pulse changes in volume from its normal character, becoming smaller and even *thready* in cases where the hemorrhage has been alarming.

III. *Changes in the Tissues.*—The third class of pathological conditions, viz., "changes in tissues, dependent on injury to vessels," is found to exist in two distinct situations: 1. In coats of the artery themselves; 2. In the tissues about the artery.

When an artery of small size is wounded, we notice frequently that without any form of treatment, not even compression for a short period, the hemorrhage ceases spontaneously and within a very short time. We notice, in the second place, that this spontaneous arrest of hemorrhage is more rapid in some anatomical situations than in others; and, in the third place, that this spontaneous arrest of hemorrhage depends somewhat on the variety and extent of the injury.

To explain the conditions to which these variations are due, and to positively reach the exact changes in tissues on which this spontaneous arrest of hemorrhage depends, has for centuries been a subject of investigation, inquiry, and dispute.

Petit, in 1731, claimed that the arrest was due not to contraction of the vessel, but to the formation of two clots—an outside clot called "*couvercle*," and an inside clot called "*bouchon*."

Morand, in 1736, added changes in the arterial coats.

Kirkland, in 1763, added the effect of decreased heart's action and sustained arterial contraction, but denied the influence of coagula.

John Bell denied contraction and *internal* coagula as a means of arrest, but advocated "infiltration of blood into the cellular tissue."

Jones, in 1805, in his wonderful essay on hemorrhage, by experiments, advanced doctrines which to this day have been little altered.

These changes, as now accepted, are as follows:

1st. A retraction of the whole vessel within its sheath occurs, due to its normal elasticity.

2d. A contraction of the entire coats of the vessel in some cases ensues, causing a conical appearance of the severed end, or, in others, a *curling* of the middle and internal coats into the calibre of the injured vessel is perceived.

3d. The formation of an internal and external coagulum is usually detected, the latter being, however, possibly absent.

4th. "Adhesive inflammation" is now excited between the clot and internal coat, also between the three distinct arterial coats, and often between the external coat and the outside tissues.

5th. Organization of the internal coagulum, with development of blood-vessels within it, and a free anastomosis between them and the neighboring capillaries, completes the process of repair.

Guthrie states that in the *distal* end of an injured vessel these changes are, as a rule, imperfectly performed; that arterial contraction is deficient, and that, for that reason, secondary hemorrhage from the distal end is most common.

A much better explanation of this latter occurrence, to my mind, is based on an anatomical alteration between the proximal and distal extremities of an injured vessel, since, in the latter, the vaso-motor nerves are frequently severed from their direct *ganglionic* attachment; and from *defective nervous* influence, reparative processes are either delayed or imperfectly performed.

SYMPTOMS DUE TO HEMORRHAGE.

When a patient expires suddenly from the impetuous bleeding of some large artery, from a ruptured aneurism or wounded viscera, the face at once becomes deadly pale, a dark circle round the eyes is perceived, the lips change to a blackish hue, and the extremities become rapidly cold. The patient faints, revives but to be conscious of his danger, and faints again. The voice is lost; there is an anxious and incessant tossing of the arms, with that restlessness which is the sign of the approaching end. The head is suddenly raised, gasping as it were for breath, with inexpressible anxiety depicted on the countenance. The tossing of the limbs continues; convulsive sighs are drawn; the pulse flutters, intermits from time to time, and the patient expires.

The countenance is not of a transparent paleness, but of that clayey and leaden color which the painter represents in assassinations and battles; and this tossing of the limbs, which is commonly represented as the sign of a fatal wound, is indeed so infallible a sign of death, that I have never known any one to recover who had fallen into this condition.

Treatment.—In the early centuries, when hemor-

rhage was with difficulty controlled, and the percentage of mortality from this source enormous, superstition frequently accompanied the defective surgical means at that time in vogue. Thus we find Wolffius, Senertus, Michael Mercates, and Gottfried Maebius, in the sixteenth century, extolling the application of roads behind the ear and in the arm-pits, as a means of arresting hemorrhage.

Plunging bleeding members into the abdomen of a living fowl had its adherents. The use of hot magnetic ore, boiling oil of turpentine, vitriol, and corrosive sublimate were also among the cruel practices of the day. The actual cautery can be found described as early as Galen. Albucasis, in his work on surgery, devotes fifty-eight chapters to the cautery and its uses. All possible designs and shapes were wrought from iron to meet the various emergencies, and plates of them published, and the special advantages of each extolled. Red-hot knives were first suggested by "Fabricius Ab Aquapendente" as a valuable improvement on former customs for the *immediate* arrest of hemorrhages during amputation.

In the reign of Henry IV., Ambrose Paré first advocated ligation, with rules and directions not unlike those of the present day; but for a century it was used with great caution, and met with much disfavor.

Petit, in 1730, urged a compress and bandage at the stump to modify the *shape of the clot*, and invented the tourniquet, known by his name. In 1732 Petit's experiments of the effect of astringents on mutton were made in his endeavor to discover artificial means to *harden* the clot within a stump by local applications.

Pouteau, soon after, advocated the ligation of *nerves* with the vessel to stimulate the swelling of tissues, and thus cause compression of the vessel. Subsequently torsion became developed by Amussat, Velpeau, and Thierry. Ligation and its mechanism have been fully explained by Jones. Tourniquets have been modified and improved by Signorini, Skey, and hosts of others, and the study of collateral circulation investigated to a high degree of perfection by Mannoir, Porta, and Stilling.

Transfusion has also been added, of the literature of which Blundell's Essay probably best deserves mention. Acupressure, devised by Simpson in 1859, has proved also a valuable contribution to this branch of surgical investigation.

To recapitulate, then, we have as surgical means of arrest:

- 1st. *Tourniquet* (a temporary measure): Petit's, Signorini's, Skey's Horse-shoe, and others.
- 2d. *Styptics*: 1. Cold used in cavities or to allay general oozing. 2. Ferri persulph. 3. Gallic acid. 4. Matico. 5. Alum. 6. Argent. nitratis.
- 3d. *Ligation*: Paré, Jones.
- 4th. *Torsion*: Galen, Amussat, Velpeau, Thierry. It is now decided that four complete turns are required to occlude the calibre of a vessel.
- 5th. *Acupressure*.
- 6th. *Cauterization*.
- 7th. *Transfusion of blood*.

I close the subject of hemorrhage by enumerating certain general rules of treatment, which seem to me to meet all possible indications.

1st. Always *ligate* the bleeding vessel, in moderate hemorrhage, when convenient to do so; the form of ligation used depending on the choice of the operator.

2d. Use compression over the wound on the *main trunk*, in moderate hemorrhage, when ligation of the wounded artery is inconvenient.

3d. In *violent* hemorrhage enlarge the wound and tie the artery.

4th. As a *rule*, never attempt ligation except when *bleeding actually exists*.

The exceptions to this rule are: 1. In *exposed* vessels of large calibre demanding ligation as a safety measure. 2. In delirium tremens following an injury. 3. When necessity for transportation exists.

5th. Ligation should, as a rule, be applied *at the bleeding point*, and not remote from it.

The reasons for this general statement being: 1. That collateral circulation may otherwise keep up the hemorrhage. 2. The bleeding vessel may not be the main trunk. 3. There exists in certain localities additional danger as you approach the heart. 4. Gangrene is liable to occur, in case subsequent ligation of the wound shall be required.

6th. Use the *external wound* as a *guide* to your incision to reach the vessel—except when the wound exists on the side opposite to the vessel injured, when a probe may be cut down upon.

7th. Always use the greatest precaution to avoid needless loss of blood in reaching the vessel, until the finger can compress it.

8th. The artery, when found, should be tied above and below the wounded portion, and at a bifurcation **THREE** ligatures should be used.

In case the lower end cannot be discovered, use *compression* in the wound as a substitute for ligation.

9th. A ligation should not be placed close below a large branch.

10th. In *recurring* hemorrhages the treatment should depend on the *color* of the blood and on the severity of the hemorrhage.

If the hemorrhage springs from the proximal end of the artery: 1. Tie, if possible. 2. Amputate, if necessary. 3. Use styptics and compression, if both are impossible.

11th. *Amputation* is preferable to ligation: 1. When great swelling of the limb renders ligation difficult. 2. When exhaustion of the patient forbids further search for the vessel. 3. When *competent assistance* is needed and not attainable.

12th. In case a large vessel is injured, without actual hemorrhage, heat and fannels to the limb are indicated as a *preventive* measure.

13th. In case an aneurism is the seat of hemorrhage—provided the aneurism is *traumatic* in its origin—it should be treated on the same principles as if it were a wounded artery.

(To be continued.)

FOREIGN BODY IN THE INTESTINES— OPERATION AND RECOVERY.

By J. C. MCKEE, M.D., U.S.A.

JOEL H. TUDOR, American, æt. 28; occupation, laborer and amalgamator at "Tip Top" Silver Mine; height, 5 feet 10 inches; weight, 185 lbs.; of a strong and muscular frame.

History.—On January 15, 1879, was performing a customary sleight-of-hand trick with a piece of copper wire about three inches in length, held in one of his hands, and which, by rapid manipulation, was made to mysteriously disappear; the lookers-on betting freely that it would be found up one of his shirt-sleeves or elsewhere. He had performed the trick so often as doubtless to have become careless as to the distance the wire was inserted or pushed into the nostril, at the same time being ignorant of the close and continuous connection between the nasal cavity and the throat or pharynx. This time, after having his

shirt-sleeves, etc., searched, and, in order to show the spectators where the wire really was, he probably threw his head back further than usual, when it gravitated, fell back into the pharynx, and passed into the stomach.

In the absence of medical advice, he at once took an ordinary store bottle of castor oil, in hopes that the wire would be safely carried through the intestinal canal. No pain in the stomach followed, and he worked steadily until the 15th of March, a period of two months, when he was idle a couple of days, owing to the mill shutting down for repairs. He was then seized with an acute pain on the right side of the abdomen, about three inches from the umbilicus. On the 16th he started in an ambulance for Prescott Barracks, distant sixty-five or seventy miles, where he arrived on the evening of the 17th. During the journey he suffered great pain from the jolting of the vehicle. A hypodermic of Magendie's solution of morphia, ℥x., gave him relief and rest. He pointed out and covered with the end of his finger a tender spot about three inches to the right and below the umbilicus. No tumor or lump was then perceptible. A slight cathartic was given him, and strict rest in bed enjoined. A lump or tumor then gradually formed, becoming more and more defined and more and more tender to the touch in the spot he first pointed out. Pulse and temperature were normal. The man insisted that the wire had lodged at this point, and the sequel proved that he was correct.

Operation.—The case from its surroundings was calculated to arouse deep sympathy and anxious solicitude as to the result. The operation was freely discussed pro and con, and Mr. Tudor being a fair type of the independent frontiersman, endowed with good common sense, determined that an operation was the only thing to look forward to for permanent relief, and insisted on its performance as soon as possible. Accordingly, on the 4th of May, all preparations having been made, the following operation was performed under Lister's antiseptic process: the surface of the abdomen over the tender spot and tumor was carefully shaved and then sponged with ether. The tender spot was located and marked by a cross scratch on the skin. The patient was etherized, and an incision about three inches in length was made through the skin, three and one-half inches to the right of the umbilicus, parallel to the border of the rectus and in the direction of the linea semilunaris. As the operation advanced it was found that the integuments and muscles were closely adherent and coalesced with each other, no doubt from sympathetic inflammation with the internal lesion, necessitating constant and great caution in the use of the knife and requiring the diligent use of the director, as the suspected spot was approached. The incision had now to be made an inch longer, in order to give more working room. It was reasonable to suppose from the condition of the integuments, that there had been sufficient exudation of plastic lymph around the foreign body to cause adhesions, not only around where it may have penetrated the intestine, but that adhesions had been made with the opposite peritoneal walls. As near as could be judged from the result, this proved to be correct. The wire gradually became more and more defined as the tissues yielded in the gradual approach. At this step in the operation it was considered best to find out if any abscess had formed, and the fine point of an hypodermic syringe was passed into the tumor. Nothing but serum filled the cylinder.

The hemorrhage was insignificant, and readily con-

trolled without ligatures. It was, I think, wisely determined not to incur the risk of opening the peritoneal cavity, but to depend upon the supposed (now almost confirmed) fact of adhesions existing between the intestines and the opposite peritoneal wall. The middle of the wire was at length seized with a pair of forceps; another pair was also applied, so that when the wire was divided between them by heavy cutting-forceps, each end was readily extracted from its bed. The wire proved to be of copper, $2\frac{1}{8}$ inches in length, No. 14 American, or No. 16 Birmingham measure. The hemorrhage having stopped, a drainage-tube was laid at the bottom of and whole length of the incision.

Silver-wire sutures to the number of three were passed through the muscles and integuments, bringing the edges close together. Three others were passed through the skin only. Antiseptic dressings were carefully applied, and firmly secured by frequent turns of bandages around the body. Fifteen minims of Magendie's solution were given hypodermically, and the patient removed to his bed. In the evening at nine o'clock he was resting comfortably. On being aroused, he recognized me, and asked about the wire. On being told that it had been found and removed, that it would not trouble him any more, he expressed an opinion about it more forcible than polite, and again relapsed into sleep.

The patient's rapid progress to recovery after the operation was very gratifying and satisfactory. The following night he was seized with a severe pain in the small of the back, for which p. opii., gr. ii., was administered with relief. A profuse perspiration, with flushed face, followed on May 6th. Both were easily controlled by the hypodermic injection of Magendie's sol., ℥x., given at required and necessary intervals. Valentine's meat juice, ʒj., diluted, was given every four or six hours. Thermometrical observations were taken every four hours; and at no time did the thermometer show a higher range than $100\frac{3}{4}^{\circ}$. Pulse averaged 112; respiration, 36. At 9 A.M. of the 6th the dressings were removed and examined under the spray. The wound looked very favorable. The dressings were reapplied. At 12.30 A.M. of the 8th, the temperature was 98° ; pulse, 98; respiration, 32. Beef essence was now given every two hours. On the 9th, was allowed egg and milk. On the 10th, the wound was redressed under the spray. Not a drop of pus was to be seen; dressings were clean and sweet. The drainage tube was removed. On the 13th, eight days after the operation, the sutures were removed under the spray. Union had taken place the whole length of the wound. Salicylated cotton, secured by a bandage, was applied, and ol. ricini, ʒj. given, with the effect of bringing away a great quantity of feces. From this time he made rapid progress to recovery. On the 19th, all dressings were removed, and he was allowed to sit up and walk around the ward and the hospital.

PRESCOTT BARRACKS, PRESCOTT, A. T., May, 1879.

EXCESSIVE LOCHIA.—Dr. Hugh Miller, of Glasgow, recommends the following in excessive lochial discharge accompanied by a relaxed condition of the uterus:

R. Quin. sulph.	ʒ ss.
Acid. hydrobrom.	f ʒvj.
Aque font. q. s., ad	f ʒij.

M.

Sig.—Teaspoonful three times daily.

Progress of Medical Science.

EXTIRPATION OF THE LARYNX.—The entire history of the interesting case in which Dr. Foulis, of Glasgow, removed the larynx, has never been published. It appears that at the time of the operation there was pulmonary disease, though in abeyance. After the third operation, the patient was admitted by his former employer to work as telegraph clerk, and for eleven months was able to keep at his post, wearing the artificial larynx night and day. Toward the end of the year, however, he noticed "occasional streaks of blood in the mucus," and the lower edge of the wound in the neck became slightly excoriated, probably from the downward pressure of the tube. On Christmas-day he was carefully examined, and was found to have advanced pulmonary difficulty, "the apices of both lungs being dull to percussion, and giving a prolonged hollow expiration-sound," "while the cough, the hæmoptysis, and the night-sweating were worse than ever before." The interior of the trachea showed extensive ulceration, presumed to be tubercular. He died March 1st, 1879. No post-mortem examination was permitted. The conclusions derived from the case are favorable, according to the operator, who intimates that the extension of a malignant disease was arrested, the patient dying of an old constitutional difficulty. He enjoyed a year of useful and comfortable existence, living, in all, seventeen and a half months after the operation, surviving it a longer period than any similar case, so far as is at present known.—*Lancet*, March 29, 1879.

MAHOMED ON BRIGHT'S DISEASE.—An interesting study of the Records in Guy's Hospital, London, by the medical registrar, Dr. Mahomed, have led him to the following conclusions with reference to the important points now at issue in the history of Bright's disease:

1. Albuminuria, though occasionally produced by other causes, is generally the result of increased pressure in the capillaries of the kidney, either venous or arterial.

2. Neither albuminuria nor dropsy are usually present in chronic Bright's disease; when present they indicate acute or epithelial changes.

3. The blood-condition which produces the high arterial pressure of Bright's disease is the primary condition, and is not secondary to deficient renal excretion, as held by Bright himself and subsequently by nearly every authority upon the subject.

4. The most generally accepted account of the disease and its symptoms fail to recognize it in by far the larger number of cases in which it exists.

5. Cases present themselves bearing the aspects of various form of heart disease, of bronchitis, of cirrhosis, of cerebral disease, and many other conditions, in which we can only discover the existence of chronic Bright's disease, as the *fontes et origo mali*, by the signs of high pressure in the arterial system.

6. The cardio-vascular changes, when found alone, may be taken as evidence of the existence of the disease.

7. Similar changes to those found in the kidneys exist also in the mucous membranes, in the skin, and in other parts.

8. The condition of high pressure is almost constantly present in old age, and, in one form or other, brings about a large proportion of the deaths in persons over fifty.

9. The existence of high arterial pressure in the

pulse of young persons indicates a diathesis, and is of grave importance.

10. The same condition, being of frequent occurrence, after the age of fifty, is not of such great importance unless present to an excessive degree; it then produces serious symptoms, and calls for active treatment.

Some of these propositions have already been enunciated by Gull and Sutton, though they have not met with general acceptance. It is plain that the root of the matter has not been reached as yet.—*Lancet*, March 29, 1878.

SECTION OF THE EPIGLOTTIS.—Dr. William Porter, of St. Louis, alluding to the recorded cases in which portions, if not the whole, of the epiglottis, has been severed, either by accident or disease, records three cases of his own, in one of which he removed three-fourths of the organ for a neoplasm. The main disturbance in such cases seems to be in phonation; the vowel sounds "a" and "e" are less distinct, and the voice harsh if the cartilage is irregular and jagged. Deglutition, on the other hand, becomes easy after a time, for the base of the tongue may so cover the larynx, and the muscles and mucous folds so close it, that the loss of the organ is largely compensated for. Usually, when ulceration sets in, the process of destruction is so slow that the parts gradually accustom themselves to the loss. After an accident, as when Murat lost a portion of the epiglottis from a musket-ball, it may be necessary to introduce an elastic tube into the stomach as an artificial aid. Dr. Porter did not find this necessary in his case, which was as follows: for some five months there had been difficulty in swallowing, with laryngeal pain and cough. On laryngoscopic examination a large nodule was found occupying three-fourths of the free edge of the organ. After some weeks of local treatment, which accomplished nothing, the diseased mass, including fully one-half of the epiglottis, was severed. Semi-solid food was then ordered, but no artificial aid was resorted to, as the long-continued disease of the part had accustomed the patient to supply its loss. The wound healed in a fortnight, and there has been little functional disturbance. The following conclusions are given: if a benign growth of the epiglottis exist, or there is malignant disease which has not as yet implicated the surrounding parts, removal of the epiglottis, or such a part of it as is involved, is practicable and justifiable.—*American Journal of the Medical Sciences*, April, 1879.

DEXTRO-QUININE AS AN ANTI-PERIODIC.—Dr. C. O. Dunlap, of Chillicothe, Ohio, has had some experience with dextro-quinine, used as a substitute for the sulphate. He has tried it in fifteen cases, and in all with success. His dose was dextro-quinine, gr. v., and ext. acconit. rad., gr. ʒ, repeated every two hours during the night. He thinks that the amount of the medicine need not be larger than of the sulphate, and he has never known it to produce ringing in the ears. His section of the country, being highly malarious, has furnished him an excellent opportunity for testing it, and he states that with it may be obtained "all the good results of the sulphate of quinine with none of the objectionable features of the latter."—*New Orleans Med. and Surg. Journal—Ohio Med. Rep.*

MALARIAL FEVER.—An interesting treatment for malarial fever is reported from Mount Sinai Hospital. Quinine, Fowler's solution, Warburg's tincture, eucalyptus, chloroform, whiskey, had all proved unavailing, when the patient was transferred from the lower to the upper floor. Thirteen days afterwards there had been no relapse.—*New York Medical Journal*, April.

THE OBSTETRIC FORCEPS.

A DECIDEDLY noteworthy debate recently took place at the London Obstetrical Society. The subject of discussion was the obstetric forceps, and the promised interest in the matter gathered not only the leading obstetricians of London, but also representatives from Dublin, Edinburgh, and many of the provincial towns of England. Dr. Robert Barnes opened the debate, and presented the subject in an admirably clear and scientific manner.

The forceps is an instrument that represents in great perfection the vagaries of the obstetrical mind and the ups and downs of surgical fashion. Even now, according to the idiosyncrasy of its particular owner, it lies in neglect and rust, or exhibits the sleekness that comes of daily application. The indications for its use, to be sure, are much more definite than formerly; still they are far from being peaceably agreed upon, and the conclusions reached by so many experienced men in the present debate may well be regarded with interest.

At the outset the question was much narrowed down and simplified by the assumption that the use of forceps in lingering labor only need be discussed, thus excluding such complications as convulsions, hemorrhage, syncope, prolapse of the cord. It was further premised that, in attempting to draw conclusions the comparison should be made between the results of the use of the forceps and its alternatives, including in the latter expectancy, oxytocics, manipulation of the uterus, and other measures.

In considering the value of the forceps, the question divides itself again into its use in low operations, when the head is in the inferior strait, and in high operations, when the head is seized at or above the brim. In the former case the parts are almost always dilated, and there is need only of a little more *vis*

a tergo for the expulsion. We may then employ either ergot, the forceps, or simple expectancy. The superior advantages of the forceps in such cases was universally conceded by those who took part in the discussion, and their decision was undoubtedly the correct one. If skilfully done—and we must base our rules upon the supposition of sufficient skill—it saves the mother much unnecessary pain, lessens the likelihood of still-birth, and last, though perhaps not always least, it saves time and inconvenience to the physician. It is in this field especially that the forceps deserves to become more popular, and the unanimous opinion of the Society on the point will doubtless have a beneficial effect. It is here, to be sure, where much of the abuse of forceps has crept in, but an operation essentially good does not deserve to be condemned on account of the liability to frequent and careless indulgence.

The principal point, however, of the discussion was in regard to the use of forceps in lingering labor when the head is at or above the brim. And here too, although there was a great deal said in developing the matter, the conclusions were tolerably unanimous. As given by Dr. Barnes, they were essentially that when in lingering labor the head is in the pelvic cavity or engaged in the pelvic brim, and it is known that there is no deformity, the forceps is better than its alternatives. Further, in lingering labor, when the head is resting on the pelvic brim, the liquor amnii being discharged, and there is slight or no disproportion, even though the cervix uteri be not dilated, the forceps is generally better than its alternatives. In proportion as the head is arrested high in the pelvis, in the brim or above the brim, the necessity, utility, and safety of forceps become less urgent. The propriety of applying forceps when the os is not dilated is the thing to be most seriously considered; but if at the time of such application the os is dilatable, it seems to be conceded that the operation is justifiable and even imperative. An analysis of the cases of Dr. George Johnston, who has been the prominent advocate for the use of the forceps in the high operation, shows that the danger is in direct proportion to the small size of the os.

Of course, as the outcome of such a discussion, we look for some new "rules for the use of the forceps." The wisdom of the Society was shown in its cautious avoidance of such committals.

One person, however, ventured the sufficiently broad assertion that the physician should never use the forceps to save his own time, and never allow the patient, if the parts are dilated, to suffer a tedious and painful labor when the forceps can relieve her.

The conclusions above indicated essentially harmonize, we believe, with the views entertained by the best obstetricians on this side of the Atlantic. They will do much to give a more definite field to the forceps, and moderate the impassioned rhetoric that is

still, in the name of meddling midwifery, poured upon that useful instrument.

In reading the discussion, however, it is impossible not to notice and regret one serious defect in the statistical method by which the conclusions were to a large extent worked out. Thus the statistics for and against the forceps bore almost exclusively upon the life of the mother and the child. But this is not enough; for, the subsequent condition of health or invalidism should also be taken into account. It counts for but little to say that the mother lived, if she lived with the parturient passage torn, with local inflammations or displacements; nor should the occasional injuries to the child fail to be considered. These points were brought up in the discussion, but not in the statistics, and until we have accurate data concerning such results, the frequency and extent of the use of the obstetric forceps will very properly continue a question open to much discussion. The opinion expressed upon this subject by Dr. T. Addis Emmet, of this city, is too important to be omitted, namely, that skilful instrumental delivery has rarely, if ever, any agency in the production of vesico-vaginal fistula, and that the direct cause of this accident is always the delay in delivery after impaction has taken place.

MEMORIAL TABLET.

WE direct attention to a request made by the committee appointed at the last meeting of the State Medical Society, to obtain the names of medical men in this State who lost their lives in the discharge of professional duties. Some years ago a memorial tablet was erected by the Medical Society of the County of New York, to those who died of ship-fever at Quarantine Hospital, and the proposition now is to make a memorial roll to be published in the Annual Transactions of the State Medical Society. We hope all will respond to the request of the committee.

REPORTS OF STATE MEDICAL SOCIETIES.

THE first in our series of reports from State Medical Societies was from Illinois, which held its annual meeting at the city of Lincoln, beginning May 20th. The usual number of papers in the various departments of medicine were read, and embraced subjects of practical interest. A report from a special committee with regard to expert evidence was presented, and additional steps taken looking towards asking the necessary legislation to secure adequate compensation for physicians who are compelled to make investigations and testify in courts of law. We hope the society will succeed in this direction.

The Medical Society of the State of Pennsylvania held its annual meeting in the city of Chester, beginning May 21. That body is evidently in good work-

ing order. The papers read were numerous, and many of them were of a high degree of excellence. Some important questions were discussed, and a slight amount of gratuitous advice given to medical journals. The question of the appointment of female insane asylum superintendents was again brought up, and secured the indorsement of the society by a rather meagre majority. The unpleasant feature of the proposed law is the clause, making the appointment of such superintendents obligatory. The important question of expert testimony did not reach a tangible form.

The Medical Society of the State of New Jersey held its one hundred and thirteenth annual meeting, at Englewood, beginning May 27th. The report of the standing committee is an important item in the transactions of the society, and this year embraced a résumé of the subject of epidemics, new remedies, and a report on necrology. Besides this report, the usual number of papers were read, and the meeting, on the whole, was a success.

The Connecticut Medical Society held its annual session in the city of Hartford, beginning May 28th. Its proceedings were characterized by the usual activity and interest. The proposed law to rid the State of medical tramps was so full of complications and vagaries that it failed to receive the support of the society. Exactly how a person can be prevented from lecturing upon any subject he may choose, providing he can obtain an audience and does his work in decency and in order, unless it be by mob interference, has yet to be determined. A committee was appointed to report upon the practicability of the metric system.

The Ohio State Medical Society held its annual meeting in the city of Columbus, beginning June 3d. Its proceedings were usually harmonious. Several valuable papers were read, and the metric system received an unmistakable rejection. The discussion was animated, and the result will, doubtless, in time, be reversed. The society adopted a commendable resolution, requesting Congress to abolish the duty on quinine.

The Arkansas State Medical Society held its annual meeting in the city of Little Rock, beginning May 14th. A State board of health was appointed, which was a step in the right direction. An interesting report upon yellow fever was made by Dr. Jennings, and reference made to some noteworthy facts in connection with the transmission of that disease.

The Massachusetts Medical Society held its annual meeting in Boston, beginning June 10th. A number of interesting papers were read, and, in the president's address, special reference was made to the question of admission of women to medical schools and the co-education of the sexes. Theoretically, it is well; but practically, it is unpleasant, if not unwise.

The Rhode Island Medical Society held its annual meeting in the city of Providence, June 10th, and we

are pleased to learn that the general interest in its welfare is increasing. The president's address was an important feature of the proceedings, and was devoted to the temperance question from a medical standpoint. The use of alcohol is proper, but its abuse leads to disastrous results. Whether the abuse and the use are not so intimately related as to render them permanent associates has been a mooted question for a long time. We incline to the opinion that the one does not necessarily follow upon the other.

The Michigan State Medical Society held its annual meeting in the city of Detroit, beginning May 11th. The proceedings were, as usual, interesting, and at times especially lively. The general results obtained seemed to be satisfactory, although the society rather unceremoniously sat down upon the metric system, not even giving it the benefit of a prolonged discussion.

CLOSE OF VOL. XV.

IN closing the fifteenth volume of the RECORD, we take occasion to express our obligations to our large list of contributors and to the members of the editorial staff for the substantial aid which they have rendered. The change in size of the journal has, we trust, added to its value, in not only giving us an opportunity for publishing lengthy papers, but in enabling us to grant greater facilities for the expression of honest opinion in the departments of reviews, reports of societies, correspondence, and new instruments. The character of the contributions which have appeared in our columns need no special notice from us, for they have been largely from men extensively and favorably known in the profession, and whose names are a sufficient guarantee for the excellence of the productions. Our working corps remains substantially unchanged, and it shall be our continued aim to increase the usefulness of the journal, at the same time adapt it to the general wants of the profession, and to make it even more acceptable to our subscribers.

In the editorial discussion of the medical topics of the day it has been our endeavor to be impartial and truthful, and if we have erred in judgment it is a failing that is human.

In order to furnish the required amount of space for accumulated reviews, society reports, and correspondence, our last number was largely devoted to these departments. With the present number we resume the publication of original lectures and other material which, for reasons already given, have been delayed.

IRRITABLE BLADDER.—Dr. Piffard, of this city, speaks favorably (*Chicago Med. Jour. and Exam.*) of a tincture of "shepherd's purse" (*capella bursa pastoris*) in this affection. Ten to thirty drops of tinct. thlaspi, as it is called and sold at homeopathic pharmacies, several times a day, he has found to act satisfactorily.

Reviews and Notices of Books.

A PRACTICAL TREATISE ON SURGICAL DIAGNOSIS, DESIGNED AS A MANUAL FOR PRACTITIONERS AND STUDENTS. By AMBROSE L. RANNEY, M.D., Adjunct Professor of Anatomy and Lecturer on Minor Surgery in the Medical Department of the University of New York. William Wood & Co., 27 Great Jones St., 1879, pp. 386.

IN order to judge of the value of a book it is well to ascertain the object the author had in view in its preparation, and then to see how far it fills the place for which it was intended. The author states in his introduction that the volume was published at the request of his private class, and adds: "As a text-book for students it will, I trust, aid memory by presenting the symptoms of disease in *marked contrast*; while, to the practising physician, it may prove a book of easy reference when questions of diagnosis arise leading towards doubt or error." It is intended then, first, for students to aid memory; secondly, for busy practitioners as a book of reference.

The book is divided into eight parts: I. Diseases of the Blood-vessels; II. Diseases of the Joints; III. Diseases of Bone; IV. Dislocations; V. Fractures; VI. Diseases of the Male Genitals; VII. Diseases of the Abdominal Cavity; VIII. Diseases of Tissue.

The diseases to be differentiated are arranged in two columns down the page, "so as to allow the symptom of each to be reviewed separately by reading from above downward, while by reading across the page the points of contrast become prominent."

One of the first requisites of such a book is accuracy, and secondly, clearness of description. The chapters on diseases of the male genitals, fractures and dislocations, are the best, while those on diseases of joints and bones contain too many errors. Thus, on page 34 the compiler states that the "constitutional disturbance in synovitis is slight." This may be true in a certain sense of the sub-acute variety, but it is certainly not so of the acute. Bryant states that "the constitutional disturbance is very great." On page 42 he states that "dislocation (of the head of the femur) is frequent in the femoral variety of hip-joint disease, and that dislocation into the pelvic cavity often occurs in the acetabular variety." It is a well-known fact that a true dislocation of the femur in hip-joint disease is rare, and that perforation of the acetabulum by the head of the bone is *very uncommon*.

The symptoms of sacro-iliac disease given are very faulty, and but little aid in diagnosis can be gained from their study.

On page 51 it is stated, in differentiating morbus coxarius from infantile paralysis, "that in the former a history of injury followed by pain in the knee, etc., is present;" in the latter, "a history of gradual loss of muscular power is present." The access of paralysis is *always* sudden in infantile paralysis, and "a gradual loss of muscular power" would exclude this disease. He makes no mention of acute periostitis, nor of disease of joints beginning in the bone. He states that "rickets does not tend to shorten life."

He lays down the rule that there is no discharge in stricture of the rectum. This may be true before ulceration has taken place. Allingham, however, states "that stricture of the rectum without ulceration is a somewhat uncommon affection." There are many other passages we had marked, but space will not allow of their reference. As a book for students "to aid memory," it cannot take the place of systematic reading,

in that it encourages them to trust to their memories without a clear understanding of the subject. With "cram-books" the archives of our libraries are already too well filled. As an aid to the general practitioner it is too condensed and contains too many errors, with only the more common symptoms of diseases to give the satisfaction obtained by consulting a more complete treatise. In regard to the chapters on dislocations and fractures, more efficient aid in diagnosis can be obtained from Hamilton's work. The chapter chiefly useful to the general practitioner is that on diseases of the male genitals. For the purposes for which the book was prepared it seems to us it has not reached the standard required. The type is large and clear, and the general appearance of the book reflects credit upon its publishers.

TRANSACTIONS OF THE AMERICAN GYNECOLOGICAL SOCIETY. Vol. III. For the year 1878. Boston: Houghton, Osgood & Co. The Riverside Press. Cambridge. 1879.

By a series of happy coincidences the third volume of the Transactions of the American Gynecological Society has finally made its appearance. It is now new, and when Dr. Goodell, of Philadelphia, reads his admirable address "On the Relation of Neurasthenia to Diseases of the Womb," he will recognize one of his ancient productions, full of careful study and suggestion. When Dr. J. C. Reeve, of Dayton, Ohio, scans his paper "On Rupture of the Perineum without Implication of the Vulva," he can have opportunity to say, "This occurred once, but it was so long ago that much might be added now." When Dr. J. Marion Sims reviews his exhaustive paper "On the Surgical Treatment of Stenosis of the Cervix Uteri," he will be pleased to know that the dust has finally been shaken from his proof-sheets; and Dr. James P. White will rejoice that his interesting paper "On Extra-Uterine Pregnancy, with Discharge of Fœtal Bones through the Bladder," has been delivered with safety, as well as his patient.

"The Necessity for Early Delivery, as Demonstrated by the Analysis of 161 Cases of Vesico-Vaginal Fistula," a paper read by Dr. T. Addis Emmet, of New York, retains its original excellence, notwithstanding its substantial appearance in his work on gynecology, issued several months ago.

Drs. H. P. C. Wilson, of Baltimore, and R. A. F. Penrose, of Philadelphia, we fear have had reason to regret the loss of life that may have occurred from a lack of the practical suggestions given in their respective papers "On the Treatment of Post-Partum Hemorrhage."

Besides the papers referred to, there are *thirteen* written by such representative men as Drs. J. T. Johnson and S. C. Busey, of Washington, D. C.; W. H. Byford, of Chicago; W. L. Richardson, of Boston; H. J. Garrigues, of New York; A. H. Smith, of Philadelphia; H. F. Campbell, of Ga.; T. Parvin, of Indianapolis; I. E. Taylor, of New York; E. Van de Warker, of Syracuse, N. Y.; A. Reeves Jackson, of Chicago; and Nathan Bozeman, of New York.

The volume contains a memorial of Edmund Randolph Peaslee, M.D., LL.D., with portrait, by Fordyce Barker, M.D., LL.D., of New York; also a memorial of Washington Lemuel Atlee, M.D., with portrait, by Dr. T. M. Drisdale, of Philadelphia.

There has been no change either in type or paper, but a worthy improvement in binding has been made, and to the volume proper has been added an "Index of Obstetric and Gynecological Literature of all Countries for the Year 1877." The latter is the work

of the Secretary, Dr. James R. Chadwick, of Boston, with the co-operation of Dr. J. S. Billings, U.S.A., in charge of the National Medical Library at Washington, and is an important and valuable addition, that reflects high credit upon the authors.

The present volume maintains the established high standing of the American Gynecological Society, and although its lustre is slightly dimmed by age, its original worth entitles it to a prominent place in the library of every obstetrician and gynecologist.

Reports of Societies.

MASSACHUSETTS MEDICAL SOCIETY.

Held in Boston, June 10 and 11, 1879.

(Special Report for THE MEDICAL RECORD.)

THE Annual Meeting of the Massachusetts Medical Society was held in the Horticultural Hall, Boston, on Tuesday and Wednesday, June 10 and 11, 1879.

The President, Dr. GEORGE H. LYMAN, called the meeting to order at noon on Tuesday, and the reading of papers was begun.

CASES OF INSANITY FOLLOWING ACUTE DISEASES.

This paper was read by DR. JAMES B. AYER, of Boston. He reported briefly two cases of pneumonia, in which, after the crisis had passed, acute maniacal symptoms supervened. In one they subsided in the course of two days; but in the second, now at the end of twelve weeks, there was marked improvement in the physical condition of the patient, but in regard to her mental condition the prognosis was uncertain. The cases reported were typical cases of insanity following and caused by an acute disease, which both poisoned the blood and exhausted the patient. Such cases could never be mistaken for delirium. The reader then discussed the difference between mania and delirium. Whether or no there was a specific difference, there was a well-marked clinical distinction between them. The transitory form of post-febrile insanity was rare, but cases of the more grave character were found in all asylums for the insane. He reported statistics which he had collected regarding the frequency of cases of post-febrile insanity as compared with other cases committed to asylums, and in conclusion stated that we could not too carefully watch the convalescence of our patients recovering from acute diseases, remembering that insanity might follow the mildest cases, and that it very frequently appeared in advanced convalescence, when the patient was considered nearly well.

In the discussion following the reading of Dr. Ayer's paper one Fellow reported that he had seen one case of acute insanity follow typhoid fever during convalescence. It recovered after residence in an asylum. Another case following mild acute pneumonia died within a week.

Another Fellow remarked that the pathological condition in such cases was probably due to malnutrition and cerebral anæmia.

A paper on

THE PHYSICIAN'S TRUE POSITION IN SOCIETY was read by DR. ROLLIN C. WARD, of Northfield.

INTESTINAL CATARRH OF INFANTS

was the subject of a paper by DR. GEORGE K. SABINE, of Brookline. He stated that many of the deaths

which were reported as resulting from cholera infantum were erroneously classed under that head. The name should be confined to those cases which ran a very rapid course, and in that and many other respects resembled true cholera. Its cessation and character were described. The affection commonly termed simple diarrhoea was referred to; it was a simple catarrh of the intestines, the usual beginning of all the other diarrhoeal diseases. The cause of the trouble might frequently be seen in the stools to be in the form of particles of undigested food. A more serious condition was that in which the intestinal follicles were more or less ulcerated. Improper food, given at improper times and intervals, an elevated temperature, impure air, and all those conditions which go to make up bad hygienic surroundings, were given as causes, and the most important points to be attended to in the treatment was of course to strive to remove those causes. As to food, if the child had been recently weaned let it be again nursed, if practicable. If not, the most appropriate food was cow's milk. A little bicarbonate of soda or of potassa added to the milk would aid in preventing the casein from coagulating in too large lumps. The soda was perhaps preferable, and half a drachm dissolved in four ounces of water, and a teaspoonful of the solution added to each bottle of milk, would often prevent serious trouble. It helped to prevent constipation.

An excellent artificial food for infants was that recommended by Dr. Channing of Providence, R. I., which consisted of equal parts of cream and water, with the addition of a little glycerine and lime-water.

In medication brandy stood first on the list. It stimulated the digestion, and, above all, allayed the pain. It might be given in doses of from five to fifteen drops in water (without sugar), once in two hours. The subcarbonate or subnitrate of bismuth, in doses of not less than ten grains, was also a valuable remedy. Opiates should be avoided if possible. The custom of giving young infants castor oil, calomel, or any other cathartic, especially after the trouble has fairly commenced, could not be too severely condemned.

An animated discussion followed the reading of the paper, one speaker remarking that in the treatment of such cases he regarded the subnitrate of bismuth as the "sheet anchor" in therapeutics. He commonly added a little carbolic acid to it. Another mentioned the good results which had followed the establishment of the diet-kitchens in Boston, where the sick poor, on an order from the district dispensary physician, could obtain fresh eggs, broth, and milk. Others advocated the use of condensed milk, some of the canned and sweetened, others of the "plain" condensed milk which was brought to the houses every other day. Another speaker thought the reader's criticism against the occasional use of castor oil was unjust. Another recommended rice-water and cream in the treatment of cases of the acute intestinal catarrh of infants. Another spoke of the good effects of discarding the bottle and tube in artificial feeding, and teaching the child to drink from a cup. Another alluded to the advantage to be derived from the cold-water bandage.

WEDNESDAY, JUNE 11TH.—SECOND DAY.

On Wednesday morning the Society reassembled, and was called to order by the President. After listening to the reading of the records of the names of sixty new and of thirty-three deceased Fellows, and of the Treasurer's report, a committee, which during the

past year had obtained the views of the Fellows of the Society regarding the list of drugs which should be placed in the proposed revised edition of the pharmacopœia, presented its report.

PHARMACOPŒIAL CONVENTION, 1880.

It was voted to send three delegates to the National Convention for the Revision of the Pharmacopœia, which is to be held in Washington, D. C., in May, 1880.

The reading of papers was then resumed.

THE TRIALS AND TRIUMPHS OF THE COUNTRY DOCTOR were described in an interesting and racy manner by DR. BENJAMIN D. GIFFORD, of South Chatham.

A paper on

INSANE DRUNKARDS

was read by DR. THEODORE W. FISHER, of Boston. The term insane drunkards should in strictness be applied only to those persons made insane by drink. Of that class there were several varieties: 1. Intoxicated persons who exhibited in some cases the phenomena of transient madness; 2. Cases of delirium tremens; 3. Patients with *mania à potu* or acute mania from the immediate effects of drink; 4. Chronic mania of alcoholism; 5. Dementia of alcoholism; and besides those there was scarcely any form of mental disease which might not in some cases be due to the abuse of alcohol. A sixth variety known as dipsomania occupied a somewhat debatable ground, some regarding it as a disease due to excessive habitual drinking, while others considered it a form of insanity due to hereditary or constitutional causes, and characterized by periodical attacks of drunkenness. It did not seem unreasonably to suppose that drink might produce in some cases simply a mania for getting drunk. The condition of dipsomaniacs was fully described, the importance shown, and yet the difficulty acknowledged of having them placed in proper asylums for a sufficient length of time.

SOME DISEASES OF THE EYE REQUIRING IMMEDIATE TREATMENT

was the subject of a paper by DR. CHARLES H. WILLIAMS, of Boston. The symptoms, differential diagnosis, pathological appearances, and treatment of glaucoma, iritis, and ophthalmia neonatorum, were discussed.

Following the introduction of delegates from other State medical societies, and the reports from delegates to other medical organizations, the

ANNUAL DISCOURSE,

entitled, *Many Things Remain to be Done*, by DR. GEORGE W. GARLAND, of Lawrence, was delivered.

The orator remarked that there was never a greater untruth uttered than the saying, "When a man has once got his name up he can lie in bed till noon." Nothing but untiring industry would enable us to advance or even to maintain the high position we now occupied. Our work could not be slighted with impunity. The reason why, in the history of the medical men of that State, that here and there one arose above the common mass of physicians was, that while he lived he did something to elevate the standard of medicine. The orator advocated the influence of the Society in securing the universal establishment of the metric system of weights and measures. Reference was made to the good work of the members of the Society in sanitation and hygiene. Much yet remained to be done in those departments of science. Regarding the admission of women to the medical schools and to the Society, the orator stated that in his opinion, if

women were to be admitted to medical schools and were to be recognized as physicians, there could be no more impropriety in co-education than there was in co-practice or co-consultation. The same qualifications should be strictly adhered to in all cases for admission into the Society, and then there could be no valid reason for excluding any human being from the Society.

After passing a vote of thanks to the orator for his able and eloquent address, the Society passed to the Music Hall, where dinner was served.

The following are the officers for the ensuing year:

For President—Dr. George H. Lyman, of Boston.

For Vice-President—Dr. David P. Smith, of Springfield.

For Treasurer—Dr. Frank W. Draper, of Boston.

For Corresponding Secretary—Dr. Charles W. Swan, of Boston.

For Recording Secretary—Dr. Francis W. Goss, of Roxbury.

For Librarian—Dr. David H. Hayden, of Boston.

For Orator—Dr. Thomas H. Gage, of Worcester.

For Anniversary Chairman for the Annual Meeting in 1880—Dr. J. C. Warren, of Boston.

The next Annual Meeting will be held in Boston, on the second Wednesday in June, 1880.

RHODE ISLAND MEDICAL SOCIETY.

Sixty-seventh Annual Meeting, held in Providence, June 10, 1879.

(Special Report for THE MEDICAL RECORD.)

THE sixty-seventh annual meeting of the Rhode Island Medical Society was held in Lyceum Hall, Providence, June 10th, the President, Dr. EDWARD T. CASWELL, in the chair.

Dr. C. W. PARSONS read the report of the trustees of the Fiske fund, as follows:

REPORT OF THE FISKE FUND.

After a careful examination of the essays presented, the trustees awarded the premium of two hundred dollars for the best essay on the "Artificial Feeding of Infants," to an essay bearing the motto *erat infans*, and found the author to be Dr. Oliver C. Wiggim, of Providence. The premium of two hundred dollars for the best essay on "Cholera Infantum; its Causes, Nature, and Treatment," was awarded to an essay bearing the motto, *Nec scire fuit omnia*, and the author was found to be Dr. Charles E. Banks, of Portland, Me. On the third subject for 1879 the trustees made no award.

They proposed the following subjects for 1880:

1. The true value of electricity in its application to surgery.

2. The sympathetic nerve—its relation to disease.

For the best essay on either of those subjects worthy of premium they offered a premium of two hundred dollars, on the usual conditions.

REPORT OF BOARD OF CENSORS.

Dr. W. O. BROWN read the report of the Board of Censors. Dr. Henry J. Bigelow, of Boston, was recommended for honorary membership of the Society, and Dr. John W. Sawyer for honorary chairman.

REPORT OF COMMITTEE ON PUBLICATION.

Dr. W. O. BROWN read the report of the Committee on Publication, giving an account of the publication of the second part of the second volume of Transactions.

REPORTS OF DELEGATES.

Dr. JOB KENYON read a report of his visit to the meeting of the American Medical Association, with notes of the papers presented there.

Dr. JAMES H. ELDRIDGE read a report of a visit to the annual meeting of the New Jersey Medical Society, with notes of the proceedings.

SUPERINTENDENTS OF THE INSANE.

DRS. RAY, KIRKBRIDE, and NICHOLS, from the Convention of Superintendents of the Insane, were introduced to the Society. Dr. Ray made a brief address, expressing his long interest in the Rhode Island Medical Society, his confidence in its increased prosperity, and making allusion to former members of the Society. Dr. Kirkbride expressed the reliance of the superintendents of the insane upon the medical profession, and spoke of the honorable record of the State of Rhode Island in its care of its insane, which he did not doubt was largely from the influence of this Society. Dr. Nichols gave some pleasant recollections of his student life in Rhode Island.

DELEGATES FROM OTHER STATE MEDICAL SOCIETIES.

Dr. J. F. NOYES, of Michigan, an honorary member of the Society, made a few remarks, regretting the necessity that compelled an almost immediate departure from the meeting, and conveying the fraternal greetings of the Michigan Medical Society.

Dr. PENNINGTON, of New Jersey, extended the congratulations of the New Jersey Medical Society to the Rhode Island Society, and expressed his personal pleasure at meeting the members.

Dr. HUTCHISON, of New York, gave some account of the organization of the New York Medical Society.

Dr. DAVIS, of Massachusetts, expressed his pleasure at meeting the Rhode Island Society, and spoke of the progress of medical science as illustrated in particular by the attention given by national and State governments to the condition of sanitary reform. Dr. BIELDY, of Massachusetts, extended the hearty greetings of the Massachusetts Medical Society.

REGISTRATION OF PHYSICIANS.

Dr. ARTEL BALLOU, from the Special Committee on Registration of Physicians, reported that the subject had not yet been fully considered, and the committee was continued.

EXPERT TESTIMONY.

Dr. JOB KENYON, from the Committee on Expert Testimony before Courts, reported that a petition had been presented to the legislature for inquiring into the subject by the Judiciary Committee, and that a measure would be brought forward and considered at the next session. The committee was continued with further powers in relation to the subject.

OBITUARIES.

The Secretary, Dr. W. E. ANTHONY, read obituary notices of deceased members of the Society: Dr. Samuel Augustus Arnold, Dr. Almond Clark Whitman, and Dr. Israel Matthewson Bowen, active members, and Dr. Ashbell Woodward and Dr. Isaac Hays, honorary members.

POISONING BY PRUSSIC ACID.

Dr. W. H. PALMER gave an account of a recent case of poisoning by prussic acid, which presented some unusual features.

The following were elected officers of the Society for the ensuing year:

For President—Dr. E. T. Caswell, Providence.

For First Vice-President—Dr. George P. Baker, Providence.

For Second Vice-President—Dr. Charles O'Leary, Providence.

For Recording Secretary—Dr. W. E. Anthony, Providence.

For Corresponding Secretary—Dr. E. M. Harris, Providence.

For Treasurer—Dr. Charles H. Leonard, Providence.

For Board of Censors—Dr. David King, Newport; Dr. Ariel Ballou, Woonsocket; Dr. J. W. Ely, Providence; Dr. J. H. Eldredge, of East Greenwich; Dr. W. O. Brown, Providence; Dr. S. Clapp, of Pawtucket; Dr. Otis Bullock, of Warren; Dr. Lloyd Morton, of Pawtucket.

The officers of the Society were reëlected without exception.

SPECIMEN OF THE PITCHER PLANT.

DR. JAS. H. ELDRIDGE presented a specimen of the pitcher plant, which feeds upon insects, and some discussion followed upon the nature and properties of the plant, Dr. Ballou speaking of its soothing effects in certain cases of small-pox.

NEW FELLOWS.

No new Fellows were elected, the nominations going over under the rules to the next quarterly meeting.

LIBRARY COMMITTEE.

The following were elected members of the Library Committee: Dr. T. C. Newell, Dr. O. C. Wiggin, Dr. G. D. Hersey, Dr. W. E. Anthony, Dr. H. S. Miller.

PROFESSIONAL SECRETS.

DR. S. W. FRANCIS, of Newport, offered a resolution to the effect that the President of the Society be instructed to petition the General Assembly for an act that no physician authorized to practise medicine be compelled to reveal information given him in the confidence of his profession in the courts of the State. The resolution was passed.

ANNUAL ADDRESS.

The President, DR. EDWARD T. CASWELL, then delivered the annual address. He commenced by paying a feeling tribute to the memory of the venerable Dr. Arnold, and passed to make some practical suggestions for the conduct of the Society, speaking of the advantage that would result from more attention by individual members to the preparation of papers on subjects of importance and interest to the profession, to be read at the meetings, and suggesting that the day of the annual meeting be changed so as not to coincide with the date of the meeting of the Massachusetts Medical Society. The main subject of the address was devoted to a consideration of

THE TEMPERANCE QUESTION FROM A MEDICAL POINT OF VIEW.

Leaving the picture of the evils of intemperance in its social aspects to others, he canvassed the uses of alcohol in health and disease. It had long been used, and was by many considered a necessity, the nations who did not use it falling back on other stimulants of a more pernicious nature. A concise and clear description of the effects of alcohol upon the human system was given, showing that it was in no respect food, and added nothing to the vital forces, but diminished the temperature. The suggestion was made that policemen should be instructed in the use of the physician's thermometer, as determining the nature of alco-

holic stupor as differing from other stupor, so that there might be no repetition of such incidents as had been known to occur, where a sufferer from apoplexy had been thrown into a drunkard's cell to die. The power and effects of alcohol as a medicine were then elucidated, showing that it could not be omitted from the materials of the physician. Considered in relation to health the question was presented as to whether the moderate use of alcohol was beneficial or not, and there was a very general and thorough array of the latest medical knowledge upon the subject in its physical and mental relations, and the conclusion was reached that, while there were some to whom total abstinence was the only safety, the moderate use of lighter wines, ale, and beer, under proper circumstances, was not injurious, and was often beneficial under the circumstances of modern life. The address concluded with the expression of the opinion that the use of the lighter alcoholic drinks would be conducive to general temperance in the present condition of society. The address was received with marks of hearty applause and approval.

On motion of DR. WINSOR, a committee consisting of Drs. Parsons, Eldredge, and Mitchell, was appointed to consider the suggestions in the address of the President.

GASTRIC ULCER.

DR. WINSOR made a report of a case of gastric ulcer.

On motion of DR. BALLOU, a copy of the President's address was requested for publication, the Doctor expressing his hearty approval of its conclusions.

The Society then adjourned to the Narragansett Hotel for dinner.

THE MICHIGAN STATE MEDICAL SOCIETY.

Fourteenth Annual Meeting, held in the City of Detroit, June 11th and 12th, 1879.

WEDNESDAY, JUNE 11TH—FIRST DAY—MORNING SESSION.

THE Annual Meeting of the Michigan State Medical Society was held in St. Andrew's Hall, Detroit, beginning on Wednesday, June 11, at 10 A.M., DR. EDWARD COX, of Battle Creek, President, in the chair.

Prayer was offered by REV. R. W. CLARK, after which the

ADDRESS OF WELCOME

was delivered by DR. WM. BRODIE, of Detroit, who, on behalf of the medical profession and the citizens, gave a cordial greeting to the members of the State Medical Society. After reviewing the commercial interests of the city of Detroit, her financial prosperity, her attractions and her enterprise, Dr. Brodie remarked: "Gentlemen, you have met here in the interests of the noblest of professions. You have met to again greet each other and renew the friendships formed in years gone by. Science is extending her benefits to our race; and the department you represent can claim its position in the foremost ranks. To prolong life, to discover the causes of disease and how to remove them, is and has been your great mission; and when dread pestilence has invaded our land, neither the fear of death nor pecuniary loss has prevented you from being the foremost in the great cause of humanity. It is an honor to be a member of such a profession; and as we meet in this hall, to review the past, to enjoy the present, and prepare for the

future, may we also remember that we, too, are mortal. May we also remember that we are one common brotherhood, laboring together for a common interest—the prolongation of human life.

I need not repeat that you are cordially welcome. Our public institutions will be open to your inspection; and the hospitality of our citizens will be open for your physical enjoyment. In the language of Michigan's motto, we bid you 'circumspice.'

Dr. Brodie, as Chairman of the Executive Committee, then made announcements regarding the hours for the sessions, and the several invitations extended to the Society.

A recess of ten minutes was then taken to receive proposals for membership. The report of the Standing Committee was presented, and the Society adjourned, to meet at 2 P.M.

FIRST DAY—AFTERNOON SESSION.

The Society was called to order, at 2 P.M., by the President.

NEW MEMBERS.

After the calling of the roll the following gentlemen were duly elected to membership in the Society: Elecutus B. Ward, Detroit; Morse Stewart, Jr., Detroit; A. M. Haight, Albion; J. Miller, Mount Pleasant; L. S. Griswold, Sand Lake; A. L. Worden, Ann Arbor; C. M. Woodward, Tecumseh; Thos. Addison, Rockford; S. H. Hagadorn, Bay City; A. W. Ricker, Fenton; Samuel S. Stephenson, Detroit; J. D. Knowles, Kendall; F. P. Kenyon, Montague; A. M. Hawes, Detroit; F. J. Jackson, Lapeer; C. W. Hubbard, Davidsburg; J. W. Robertson, Detroit; Victor C. Vaughan, Ann Arbor; C. P. Felshan, Ypsilanti; R. W. Odell, Ypsilanti; C. W. Morse, Dowagiac; Eli Woodman, Farmington; C. J. Lundy, Detroit; Charles S. Sheldon, Greenville; M. K. Ross, Detroit.

PRESIDENT'S ADDRESS.

Dr. Cox then delivered the annual address, selecting for his subject

CRIMINAL ABORTION.

It was an exhaustive discourse upon the evils and results of the practice of abortion, and a review of the various means suggested for doing away with the great evil. He believed that the church, the press, and the medical profession should unite in educating the people to thoroughly understand the causes and sinful results of this most cowardly crime, and to make known the fact that it could no longer be committed with impunity. The address was well received, and was referred to a special committee.

Reading of papers being next in order

Dr. E. P. CHRISTIAN, of Wyandotte, read a paper entitled

SHORTNESS OF THE UMBILICAL CORD A CAUSE OF RETARDED LABOR AND ACCIDENT.

The paper was referred to the Committee on Publication.

HODGKIN'S DISEASE.

Dr. GEO. K. JOHNSON, of Grand Rapids, read a comprehensive paper on the above subject, and gave a detailed history accompanied with photographic illustrations of two cases.

The paper was referred to the Committee on Publication, and the Society adjourned to the steamer Gazette, which took the members and invited guests to several points of interest on the Detroit River.

EVENING SESSION.

In the evening the Executive Committee gave the Society a reception at the residence of Dr. Wm. Brodie, whose hospitality and happy faculty of making guests feel as though at home are well understood both by the profession and the public.

THURSDAY, JUNE 12TH.—SECOND DAY.—MORNING SESSION.

The Society met at 10 A.M., and was called to order by the President.

REPORT OF COMMITTEE ON ADMISSIONS.

The Committee on Admissions recommended the following gentlemen for membership: Drs. L. S. Stevens, Albert P. Prescott, L. W. Bliss, J. Vohan, James H. Stowell, E. C. Adams, A. H. Green, A. J. Hope, Judson Bradley, G. W. Church, A. W. Nichols, J. W. Elliot, J. G. Millsbaugh, and G. W. Montgomery. The report was accepted and adopted.

Dr. G. E. RANNEY, the Secretary, announced a charge by Dr. Eugene Smith, in respect to the sign business, against a member of the Society, which was referred to the Judicial Council.

REPORT OF COMMITTEE ON NECROLOGY.

Dr. Wm. F. BREAKEY, of Ann Arbor, read the report of the Committee on Necrology. He was happy to report only few deaths; but the members lost had been valued ones. Drs. J. H. Beach, of Coldwater; Dwight Nimms, of Jackson; Z. E. Bliss, of Grand Rapids; and Nathan Mitchell, of Colon, were reported as having died, and appropriate resolutions from the local societies were appended to the notice of decease. The report was adopted and ordered published.

TREASURER'S REPORT.

The report of the Finance Committee was read by Dr. PRATT, of Kalamazoo. The balance in the treasury was \$181.12. The report was accepted and adopted.

A paper on *Hour-Glass Contraction of the Uterus*, prepared by Dr. J. S. CALKINS, of Thornville, was read by Dr. HUGH McCALL, of Lapeer.

The paper was discussed by Dr. J. H. BENNET, of Coldwater, and referred to the Committee on Publication.

Dr. DONALD McLEAN, of Michigan University, read a paper on

CLINICAL NOTES ON OVARICTOMY.

It was listened to with great attention and contained his experience in several cases.

The paper was discussed by Dr. A. W. ALVORD, of Clinton, and referred to the Committee on Publication.

WELLS vs. BEEBE, OF HOWELL.

The committee to whom was referred the charges preferred by Dr. C. V. Beebe, of Howell, against Dr. Wm. L. Wells, of the same place, reported as follows: We find that the Livingston County Medical Society, after a full examination, exonerated the said Dr. Wells from all the charges and specifications. While we find that there might have been some irregularities in the use of a certain cancer powder, we think it was made a reason for a professional and personal quarrel between the parties, which, in our opinion, is reprehensible, and should be discontinued. And in consideration of the fact that Dr. Wells has discontinued the irregular practice, made known the formula—the valuable formula—(which he was to

hold till death), we recommend that he be admitted to membership of this society. The "valuable formula" was a little arsenic.

The recommendation was supported.

DR FOSTER PRATT, of Kalamazoo, moved the reference of the recommendation to the Judicial Council.

DR. A. B. PALMER, of Michigan University, said it seemed to him the precedent had been already established of not going behind the returns of a local society. He therefore thought Dr. Wells should be admitted.

DR. PRATT said he did not consider that, because a local society had admitted a member, the State society should do so necessarily. The Judicial Committee room was the place for all discussions of a personal nature. "We have erected a tomb of the Capulets, in which all those things can be consigned to oblivion, except so far as it chooses to give up in part what is committed to its trust." He read a section of the constitution of the Society, as follows:

"All questions of a personal character, including complaints and protests, all questions on credentials, shall be referred at once, after the report of the Committee on Admissions or other presentations, to the Judicial Council, and without discussion."

THE CHAIR—This will be so referred without discussion.

A paper written by DR. H. O. HITCHCOCK, of Kalamazoo, was then read for him by Dr. Dunster. It was entitled, "*A Case of Fracture of the Acetabulum, with Dislocation of the Femur; Reduction and Subsequent Redislocation caused by Improper Removal of the Patient; Final Reduction after Six Weeks. The History of a Suit for Alleged Malpractice; Review of the Testimony in the Case; Decision of the Supreme Court, and Final Result of the Case.*"

This paper gave rise to a lively debate, participated in by Drs. E. W. Jenks, Hitchcock, Carstens, H. O. Walker, Brodie, and Palmer, during which questions of privilege were asked, protests and appeals from the decision of the Chair made, and motions of reference offered. The debate terminated by a continuance of the reading of the paper. The reading was again interrupted at 12.30 by a motion to adjourn, and the Society adjourned to meet at 2 P.M.

SECOND DAY—AFTERNOON SESSION.

The Society was called to order at 2 P.M. by the President, and the following candidates elected to membership in the Society: Dr. Wm. Zimmerman, and Mrs. Dr. F. A. Tenny.

NOMINATING COMMITTEE.

On motion of DR. BRODIE, of Detroit, a Committee on Nominations was appointed, consisting of Drs. J. H. Jerome, of Saginaw City, A. F. Kinnie, of Ypsilanti, H. B. Shank, of Lansing, Peter Klein, of Detroit, and E. Twiss, of Athens, to nominate all officers of the Society, except the President and members of the Judicial Council.

The Society then proceeded to ballot for President, and DR. GEORGE K. JOHNSON, of Grand Rapids, was elected.

COMMITTEE ON THE PRESIDENT'S ADDRESS.

The special committee to whom was referred the President's address on the subject of "Criminal Abortion" consisted of Drs. Foster Pratt, of Kalamazoo, Charles Shephard, of Grand Rapids, S. S.

French, of Battle Creek, E. P. Christian, of Wyandotte, and I. E. Brown, of Monroe.

JUDICIAL COUNCIL.

By ballot, Drs. Wm. Brodie, and J. A. Brown, of Detroit, and J. H. Bennett, of Coldwater.

Dr. Foster Pratt, of Kalamazoo, was elected a member of Judicial Council, to fill vacancy caused by the election of Dr. Johnson to the presidency of the Society.

Dr. H. B. Shank, of Lansing, was elected to fill the vacancy caused by the death of Dr. Nims.

HONORARIUM TO THE SECRETARY.

On motion, one hundred dollars was voted to the Secretary, with the thanks of the Society.

REPORT OF THE COMMITTEE ON NOMINATIONS.

The Committee on Nominations reported as follows: For *First Vice-President*—Dr. J. T. Thomas, of Bay City.

For *Second Vice-President*—Dr. H. B. Shank, of Lansing.

For *Third Vice-President*—Dr. W. F. Breakey, of Ann Arbor.

For *Fourth Vice-President*—Dr. E. S. Snow, of Dearborn.

For *Treasurer*—Dr. Geo. W. Topping, of De Witt.

The report was accepted.

DR. SHANK moved to amend by substituting for his own, the name of Dr. D. O. Farrand, of Detroit. Carried.

The report was then adopted.

DR. BRODIE moved that the regular order be proceeded with.

DR. JEROME moved that the further reading of the paper of Dr. Hitchcock be dispensed with. Lost.

DR. JEROME moved that those who have papers here have leave to file them with the Publishing Committee. Carried.

DR. McLEAN moved that the Society have an evening session. Lost.

DR. HITCHCOCK'S PAPER AGAIN.

DR. DUNSTER then proceeded with the reading of the paper of Dr. Hitchcock, reading extracts from the testimony in the famous case of Burgett vs. Stillwell impleaded with Hitchcock, the suit in question. The paper also quoted the decision of the Supreme Court on the trial, which reversed the judgment of the court below, and the subsequent dismissal of the case in the Circuit Court.

Considerable discussion ensued regarding the disposition to be made of Dr. Hitchcock's paper.

DR. HITCHCOCK finally asked leave to withdraw his paper from the Society, and his request was granted.

THE METRIC SYSTEM.

DR. DE WITT C. WADE, of Holly, presented a communication on the metric system of weights and measures, which was tabled until next year.

On motion by DR. BRODIE the unread papers were referred to the Committee on Publication.

On motion by Dr. Brodie, the thanks of the Society were tendered to the President, for the able manner in which he had presided over the Society during the past year and at the present meeting.

THE PRESIDENT appropriately responded.

On motion of DR. FOSTER PRATT, of Kalamazoo, the Society adjourned to meet in Grand Rapids, at 10 A.M., on the second Wednesday of May, 1880.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, June 2, 1879.

DR. J. C. SHAW, PRESIDENT, IN THE CHAIR.

FUNCTIONAL NERVOUS DERANGEMENTS SIMULATING STRUCTURAL DISEASE OF THE HEART, AND THE VALUE OF ELECTRICITY IN THEIR TREATMENT.

DR. A. D. ROCKWELL read a paper upon the above subject, of which the following is an abstract: If it was true, many to-day unconscious of danger to-morrow succumbed from organic heart disease, it was equally true that others were living a life of terrible expectancy, because of a fixed but unfounded suspicion of structural disease or decay. To illustrate that statement Dr. Rockwell referred to a case in which there was but a faint suspicion of any cardiac disturbance, although death occurred from dilatation and rupture of the right auricle; also to one in which the patient, ten years ago, was told by a distinguished auscultator that his life would be prolonged for only one or two years, but who was suffering from a nervous affection, and was not the victim of either well-marked or serious organic cardiac lesion. Correct diagnosis, therefore, in cases of suspected heart disease was of the greatest importance, and fortunately, as a rule, there was no very great difficulty in arriving at correct conclusions. Valvular disease, hypertrophy, and dilatation, with ordinary care could be detected, but with reference to fatty degeneration as much could not be said. Further on, however, the latter condition became so well defined that in most cases a probably correct diagnosis was usually readily reached. If the first sound was short and faint, its action slow and irregular, and, as associated symptoms, there were præcordial oppression with palpitation after undue exertion, a tendency to pallor and syncope, and inability to rest with the head quite low, it was quite probable that fatty degeneration was present, especially if dilatation existed without evidence of valvular lesion. Yet he had been led to believe that nearly all those symptoms might be present without the presence of structural decay. Every grade of cardiac disturbance followed long courses of dissipation, notably these of a sexual character. Cardiac disturbance was also very liable to occur during the sexual formative stage in young women. In a case related, the patient frequently suffered from what to her was alarming, namely, a feeling as if the heart suddenly ceased beating, and yet it was certain that she had no valvular lesion, and at her age (eighteen) fatty degeneration could hardly be allowed. The point impressed was that in not a few instances of disordered action of the heart, of a sufficiently persistent and distinctive character, not only to suggest, but to render highly probable the existence of structural derangement, the whole array of symptoms might be simply a sequence of physical and mental abuse by which the nervous system had been exhausted, while the heart was structurally sound. Rest, time, and treatment were the only means by which we could be certain of the existence or non existence of decay. In that connection the history of two cases was given, which illustrated the remarkable sameness of the symptoms that resulted from organic heart disease and simple functional nervous derangement.

CASE I.—Mr. C., æt. 28, led a course of dissipation for several years, apparently without injurious results. At the age of twenty he began to be conscious of palpitation of the heart subsequent to excesses. Prudence with alleviation of symptoms, and dissipation

with return of symptoms alternated until twenty-four, when he suddenly suffered from syncope, which, with varying degrees of severity, was subsequently repeated. He also coincidentally suffered from disturbance of vision, falls without loss of consciousness, and violent tremors. His condition remained nearly stationary for three years, when the attacks became more frequent, occurred every week, and he was soon rendered helpless. The rhythm of the heart was somewhat disturbed, but there was no evidence of serious structural disease. To the tonic effects of general faradization the patient had not been subjected, and that plan of treatment was begun by Dr. Rockwell in October, 1878. The patient had steadily improved from that time, and although not entirely relieved of all symptoms, he was able to attend to his business steadily. The first effect of the treatment was to diminish the frequency of the syncopal attacks, lessen the pain in the præcordial region, decrease the disturbance of rhythmical action, and to increase the strength of the pulse.

CASE 2.—Mr. D., æt. 47, after several months of unusual mental exertion, became conscious of acceleration of the heart's action and a sensation of breathlessness after slight exertion, especially that made in ascending stairs. He suffered from insomnia, and was especially uncomfortable except his head was well raised in bed. After a time those symptoms became associated with a general neurasthenic condition, loss of appetite, and nausea. The first sound of the heart was so faint and abrupt as to be hardly perceptible. The patient firmly believed that he was suffering from incurable organic disease of the heart. Under rest, and the use of digitalis and bromide of potassium, there was an appreciable, though not a very decided change for the better. Eleven months after he first came under Dr. Rockwell's care he performed some work in way of balancing business accounts, and, immediately following a short walk exposed to the sun's rays, he fell to the floor unconscious. Subsequent to that attack he experienced a disagreeable sensation in the præcordial region, with shooting pains down the left arm, and recurring with tolerable regularity every evening. His pulse rarely arose above fifty-five. Digitalis and quinine were prescribed, and general faradization administered. At the end of the first sitting, fifteen minutes, the pulse had risen seven beats. A decided feeling of invigoration followed, and a more restful night than had been experienced for months. The faradization was repeated every other day. The heart's action became more regular and frequent, the pains down the left arm disappeared, and, at the present time, he was entirely recovered.

With reference to the value of electricity to give tone and strength to the nervous system, Dr. Rockwell remarked there was but little difference of opinion among those who had had any adequate experience in its use. In thus speaking of it he did not refer to its local use alone, but to thorough, systematic, and carefully graduated applications to the whole body. It had been termed a grape-shot method of procedure, but it was such in no greater measure than the administration of any internal medicine which performed its function through its action on the whole nervous and circulatory system, or the act of sea-bathing, or the action of sunlight. Neither local nor general applications of electricity exerted a very marked influence upon the normal pulse, but in those conditions of nervous derangement in which it was so rapid, and in others in which it was so slow, the effect of general faradization was

very great. He had succeeded in reducing a pulse of 150 or 160 by 40 or 50 beats to the minute within a very short time. Even in cases in which the irritability of the heart had been supposed to be of a reflex character, that result had been obtained. He had not in such and analogous cases been able to produce results as satisfactory with the galvanic current or with local applications.

Dr. Rockwell closed his paper with the following brief statement of what much observation had taught with reference to general faradization:

In *health*, the first, and, as a rule, the only effect following an application of general faradization, was one of invigoration, which, in the course of a few hours, more or less, subsided.

In *pathological conditions*, however, five groups of effects had been most frequently observed:

First, and perhaps most frequently—providing always that the applications were not too strong, were carefully graduated, and in all respects given judiciously—the treatment was followed, as in health, by a feeling of invigoration alone.

Second. Invigoration might be followed by depression, and that again by invigoration.

Third. The immediate result of the application might be depression with subsequent invigoration.

Fourth. No immediate effect might follow, but in a short time depression was experienced, succeeded in a few hours or on the day following by invigoration.

Fifth. Depression might immediately follow, succeeded by no feeling of invigoration.

In the latter cases the treatment should be discontinued. Such cases, however, were rare.

The special effects of general faradization varied even more than did the general effects.

WIND SPASM.

DR. WM. J. MORTON presented a patient, who for several years had suffered from sudden attacks of great distress, both mental and physical, and with apprehensions of impending evil, attended by eructations of immense quantities of wind. The seizures lasted from one-half to one or two hours, during which time gallons of air, apparently, were expelled, and the patient was greatly distressed and showed an anxious expression of countenance. The attacks were liable to be developed by any form of excitement. None of the members had seen a case exactly like it. Nothing in way of treatment had afforded any benefit.

HEPATIC ABSCESS.

DR. WM. A. HAMMOND reported a case of hepatic abscess which he had operated upon April 21, 1879, evacuating about $\frac{3}{4}$ viij. of pus. Dr. Morton administered the anæsthetic. The patient had been hypochondriacal, in fact, almost insane. He had been in a private institution for treatment of mental disturbances, and had been affected in that manner four years. It was only recently that the doctor suspected any trouble with the liver. On the 21st of April he made a puncture between the 9th and 10th ribs to the depth of an inch and a half, and obtained odorless pus, which, upon microscopical examination, gave no evidence of the presence of hepatic tissue, and there was no evidence that it contained bile. The most troublesome feature in the case was the tendency to repeat, over and over, the same thing in the mind. For example, if he heard some phrase, he was unable to stop repeating it, and it would "run in his head" the same as a tune. He also had a constant impulse to blasphemy, which gave him great annoyance and mental anxiety, because he was a religious man. Since the

operation all that mental disturbance had disappeared; he had gained in weight fifteen pounds, and had slept well. There were no external physical signs of abscess, but there was a slight tenderness upon pressure.

The theory entertained by Dr. Hammond was that the brain disorder induced the liver trouble, and not contrarywise, as was more commonly supposed.

DR. A. D. ROCKWELL related the following case:

In May, 1878, a boy, aged ten, who was recovering from an attack of scarlet fever, was subjected to a severe and sudden fright by the excitement and confusion attendant on the accidental ignition of the curtains of the room in which he was convalescing.

The following night he suffered from several convulsive seizures, by which he was much exhausted, and shortly after choreiform disturbances became manifest.

The head was violently drawn from side to side through clonic contractions of the sterno-cleido-mastoid muscles, and at the same time there was distortion of the mouth, with much frothing. In September, nearly five months subsequently, the patient fell under his observation, suffering from symptoms substantially the same as described. He was subjected to electrical treatment, mainly by the method of central galvanization, and in a few weeks had approximately recovered, and treatment was abandoned. In November the patient returned with symptoms as aggravated as before. The same treatment, and in addition, general faradization, was again attempted. Partial recovery followed in due course, but for unavoidable reasons the patient abruptly abandoned treatment a second time.

About the middle of December the patient again presented himself, with the clonic movements as fully pronounced as ever. The same method of electrization was used as before, together with hypodermic injections of eserine, the active principle of physostigma, or calabar-bean. The amount injected on each occasion was $\frac{1}{10}$ of a grain, and Dr. Rockwell was led to give it a trial because of favorable reports that he had seen. The patient gradually recovered, but with no greater rapidity than on the two former occasions, and with the difference, that since the last result there had been no relapse. It had been his experience, and he believed of most practitioners, that the general tendency of chorea was toward recovery, and it was that fact that was the cause of such a surprising lack of unanimity concerning its treatment. When taken in hand immediately, it was by no means possible in every case to decide whether the recovery that followed was due to the remedy employed, or to time and care alone. If, however, the symptoms continued without abatement for two or three months, they were often exceedingly intractable to treatment, and should recovery result in a reasonable length of time after the adoption of any special method, it was fair to attribute it to the treatment employed. In chronic cases he had been led, through some considerable experience, to regard electricity in some form as a most efficacious remedy; but in the case just related, which in its details seemed to him to be somewhat unique, it would certainly appear as if the injections of eserine very effectively supplemented the electrical treatment.

The Committee on the subject of Insane Asylum Abuses then made a provisional report, after which the Society adjourned.

THE PLUMBER AND SANITARY ENGINEER has been enlarged, and changed from a monthly to a semi-monthly journal. The change indicates prosperity.

Correspondence.

NATIONAL BOARD OF HEALTH AND HOMEOPATHY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In answer to "X," in your edition of April 26th, allow me to say, Dr. Verdi is the same homœopath whose appointment some years ago, as a member of the Washington Board of Health, caused such an excitement in the local Medical Society. "X" seems to be offended that the President should have appointed this Dr. Verdi a member of the National Board of Health, and insinuates disciplining the other members of the Board should they sit with him, and that the American Medical Association should, at its approaching session, take notice of it, which means, of course, that the Association should show its displeasure in some active manner. Let us look at this matter square in the face, without prejudice, for this is not the age of bigotry.

This Board of Health is a *National Board of Health*, as its name implies,—not an Allopathic, Eclectic, Hydropathic, Thomsonian, nor Homœopathic Board of Health. The act of Congress constituting this board does not state that its members shall all be physicians, and, in fact, one of its members, Samuel F. Phillips, Esq., is not a physician. Neither does it stipulate the medical practice that each member shall employ. How does brother "X" know but what Mr. Phillips is a homœopath. This Board was not organized to carry out any one idea of medical practice, but as a Sanitary Board, and the appointment of members was made from among those known as sanitarians, and those well fitted for the positions. Dr. Verdi is a well-known sanitarian, whatever therapeutic law in the administration of medicine he may have adopted.

The spirit which is being manifested in some sections of the country against homœopaths is not the spirit of the age, and I am glad to say, for the credit of the medical profession, that that spirit is gradually hiding its head. We cannot help acknowledging that *very* many of the homœopathic physicians are educated men, having been educated in both schools, graduating side by side with us, some of them taking prizes at our colleges, and yet, because they may choose to administer their remedies according to the law "*Similia*" instead of the law "*Contraria*," we immediately ostracise them from all social and professional privileges, as far as lies in our power. Their practice is no more "based upon an exclusive dogma" than ours; their educated men do not reject "the accumulated experience of the profession" any more than we do, in fact they search further than we do; their "anatomy, physiology, pathology, and organic chemistry" are the same as ours; they use the same palliatives that we do; the only point upon which we differ is in the administration of remedies. If the truth was known, many of our own school carry their small pocket-case of tinctures, and administer their remedies according to the homœopathic law, but are not honest enough to acknowledge it.

I have much more respect for the man who practices openly what he thinks is best, without fear of the American Medical Association, or any other Associations, than for him who practices one thing and preaches the other. The medical profession is a liberal and charitable profession, and the physician who stands upon any other ground than this is a bigot, and in this age bigotry will never thrive.

I hope to see the day when the bitterness now existing (the same as existed between religious sects fifty years ago) will be wiped out; when the physicians of both schools will meet together, and consult together, and the best known remedial measures in both schools be used mutually for the benefit of mankind. B.

A RICHMOND, VA., JUNE 1, 1879.

UNION MEDICAL SOCIETY—REPORT OF CASES.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—At the last quarterly meeting of the Union Medical Society of Washington, Warren, and Saratoga counties, held at Sandy Hill, May 20th, Dr. A. B. Burger, of Gansevoort, reported a post-mortem held by himself in company with Dr. B. J. Murray, of Wilton, which disclosed an unusual condition of the pelvic viscera. A fibroid tumor was found anterior to the bladder, and an abscess as large as a goose-egg posterior to that organ. The walls of the bladder were thickened, and adherent to the pelvic walls. There had been progressive atony of the bladder and some tenderness over the pubic region. The tumor had been diagnosed before death, but the other abnormal conditions were unlooked for.

Dr. Adamson, of Lake George, reported an extraordinary case of childbirth which had occurred in his practice. Labor came on at seven months, and the entire contents of the uterus, weighing five and a quarter pounds, were expelled in a single mass, with unruptured membranes.

Dr. Gibbs read a report, furnished by Dr. Sarah J. Finch, of Fort Ann, of a case of cancer involving the external meatus of the urethra, in which the patient showed a remarkable tolerance of morphia, given hypodermically. The report stated that the solution had been administered in this manner more than 1,500 times within fourteen months. No abscesses of phlegmon had resulted, except in one instance. A case of chronic softening of the spinal cord, illustrating in a more marked degree even the tolerance of the system of hypodermic injections of morphia, was reported by the secretary. In this case, the needle had been used from six to twelve times daily for six months, and no abscess or sore of any kind had ever resulted from the puncture.

JAMES S. COOLEY, M.D.,
Sec. Union Medical Society.

SANDY HILL, N. Y., May 21, 1879.

ELECTRICITY AND EXUDATION OF MERCURY FROM THE SKIN.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—Mr. J. called at my office Wednesday morning, April 23d, complaining of nervous exhaustion. I recommended electricity and applied the galvanic current. I was astonished after the sitting, to find a couple of fine globules of mercury exuding from the pores of the skin on the back of the hand in which he held the positive electrode. I repeated the application of electricity, and another fine globule came from a point adjacent. Other applications gave no mercury.

The patient tells me that three days previous to this he had taken, upon retiring to bed, hydrarg. pil., gr. viij., thinking that his liver was torpid. This was followed by a scidlitz powder the next morning; a satisfactory passage from the bowels being the result.

He tells me, moreover, that he has not been under mercurial treatment, and has not had the metal about him in any form, with the exception of the above instance, in months.

The only source, therefore, we can refer it to, is the hydrarg. pil., absorption having taken place.

The case is an interesting one from the fact that it shows what may be the result of allowing mercury to remain undisturbed in the bowels so long, when cathartic action and not absorption is desired, and also that electricity may prove a means of aiding the elimination of the metal from the system, when such action is desired.

There was no tendency to ptyalism in this case.

H. A. FAIRBAIRN, M.D.

BROOKLYN, 239 McDONOUGH STREET.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from June 15 to June 21, 1879.

WOLVERTON, W. D., Major and Surgeon. Granted leave of absence for four months. S. O. 140, A. G. O., June 13, 1879.

DE HANNE, J. V., Capt. and Asst. Surgeon. Fort Concho, Tex. Granted leave of absence for one month on Surgeon's certificate of disability, with permission to leave the Dept. S. O. 123, Dept. of Texas, June 12, 1879.

HALL, J. D., Capt. and Asst. Surgeon. Relieved from assignment to duty at Fort Griffin, Tex. (S. O. 83, C. S.), and assigned to duty as Post Surgeon at Fort Concho, Tex. S. O. 121, Dept. of Texas, June 10, 1879.

HAVARD, V., 1st Lieut. and Asst. Surgeon. Assigned to duty as Post Surgeon at Fort Johnston, N. C., relieving Asst. Surgeon, B. G. Semig, who will comply with S. O. 114, C. S., A. G. O. S. O. 95, Dept. of the South, June 16, 1879.

WILCOX, T. E., 1st Lieut. and Asst. Surgeon. Assigned to duty as Post Surgeon, Boise B'ks, Idaho Ty., relieving Asst. Surgeon Wm. R. Hall. S. O. 64, Dept. of the Columbia, June 5, 1879.

HALL Wm. R., 1st Lieut. and Asst. Surgeon. When relieved, to report to Major John Greene, 1st Cav'y, commanding troops in the field at Camp Winfield Scott, Kittitas Valley, W. T. S. O. 64, C. S., Dept. of the Columbia.

YEOMANS, A. A., Capt. and Asst. Surgeon. Having been found by an Army Retiring Board incapacitated for active service, granted leave of absence until further orders, on account of disability. S. O. 141, A. G. O., June 14, 1879.

POISONING BY CARBOLIC ACID EMPLOYED BY INTRA-UTERINE INJECTIONS.—After the removal of a fibrous tumor of the cervix, Dr. Rheinstadter employed intra-uterine injections of a ten per cent. solution of carbolic acid. One day he noticed that only a small portion of the solution escaped, and the patient suddenly fell back unconscious. The face was pale and covered with sweat; the extremities were seized with tonic convulsions; the respiration ceased for a time, and then became slow and superficial; the pulse could scarcely be counted; and the abdomen became distended. Death seemed imminent, and the body was already cold. A subcutaneous injection of tincture of musk and ether was administered, and the pulse at once improved. At the end of four hours the patient regained consciousness. The accident was not followed by general peritonitis.—*Lyon Medical.*

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT.—Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending June 21, 1879.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
June 14, 1879.	0	11	114	2	65	24	12	0
June 21, 1879.	0	4	103	2	40	28	1	0

MEMORIAL TABLET.—At the last session of the N. Y. State Medical Society, the undersigned were appointed a committee to obtain the names of those members of our profession in this State who have lost their lives from being killed or wounded in battle, and of those who died in consequence of volunteering to render professional service during the prevalence of an epidemic or any deadly disease, or in consequence of exposing themselves through devotion to the pursuit of scientific investigations for the advancement of the science of our profession.

The list, when obtained, is to be published annually in the proceedings of the Society, in a separate roll.

Please give a short sketch of any physicians in your county who come under above description, with the date and occasion of their deaths, addressed to the chairman of the committee, Dr. Theodore Dimon, Auburn, N. Y., at as early a time as convenient, and oblige,
Yours respectfully,

Committee. { THEO. DIMON, M.D.
 { H. D. DIDAMA, M.D.
 { WM. MANLIUS SMITH, M.D.

CENTRAL TURKEY COLLEGE.—At Anitab, Turkey, is located Central Turkey College, which hopes soon to have a medical department. In a letter from President T. C. Trowbridge, dated April 30, 1879, we learn that a dispensary was established in 1876, and that work on the foundations for a hospital has been commenced. We hope the college will be successful in obtaining a permanent place for clinical instruction.

ALCOHOL IN PHTHISIS.—Dr. M. L. James recommends the following formula for giving his remedy in disguise:

R. Syr. cal. lacto-phosph..... f ℥ ij.
Spts. frumenti..... f ℥ viiss.
Glycerinæ pur..... f ℥ vj.
Tr. cinchon..... f ℥ iss.
M. Dose: according to indications.

BOOKS RECEIVED.

ELEMENTS OF MEDICAL CHEMISTRY. By ADOLPH WURTZ, Professor of Chemistry of the Faculty of Medicine of Paris. Translated, from the Fourth French Edition, by Wm. H. Greene, M.D., of Philadelphia. One hundred and thirty-two illustrations. Philadelphia: J. B. Lippincott & Co. London: 16 Southampton St., Covent Garden. 1879.

DISEASES OF THE INTESTINES AND PERITONEUM. By BRISTOWE, WARDELL, BEGBIE, HABERSHON, CURLING, and RANSOM. Wood's Library of Standard Authors. New York: William Wood & Company. 1879.

ATLAS OF HUMAN ANATOMY. Illustrated. By R. J. GODLEE, F.R.C.S. Part 2. Philadelphia: Lindsay & Blakiston. 1878.

INDEX.

A.

- A strange fact, 312, 397.
- Abbott, Dr. Geo. E., tenaculum seissors, 503.
- Abdominal pregnancy, cases of, 18.
- Abdominal tumor, rare form of disease, 348.
- Abortion, hemorrhage during, 232; septicæmia following, 534; treatment of hemorrhage in, 220.
- Abscess, bony, 446; hepatic, 620; hyperdistention of, 25, 144; of kidney, successful aspiration of, 251; of the liver, following dysentery, 176; mammary, treatment of, 402; multiple, of bladder, 355; scrofulous, traumatic origin of, 293; spinal, 395.
- Abuse of medical charity, 578, 586.
- Academy of Surgery, Philadelphia, 551.
- Acetonæmia, 301.
- Acid, acetic, in ununited fracture, 301; carbolic, poisoning by, 622; pyrogallie, in hæmoptysis, 576; salicylic, in dyspepsia, 576.
- Acidulated water in cystitis, 141.
- Aene rosacca, 371.
- Aconite, case of poisoning by, 128.
- Actual cautery, surgical uses of, 289; use of in medicine, 442.
- Acupuncture, 431.
- Adeno-carcinoma of cheek, 88.
- Adenoma, cystic, of the breast, 234; of the uterus, 13.
- Adulteration of food and medicine, 154.
- Adulterations and social science, 63.
- Anæsthetic, local, 288.
- Aneurisms, elastic bandage in the treatment of, 179; popliteal, treatment of, by Esmarch's bandage, 288.
- Adirondack region and pulmonary phthisis, 385, 409.
- Adulteration of wine in France, prevention of, 135.
- Africa, climate of, for consumptives, 252.
- After-pains, hypodermics of morphine in, 312.
- Agnew, Dr. C. R., cataract extraction, with cases, 250, 447.
- Agnew, Dr. Hayes, notice of book by, 16.
- Aids to chemistry, 331.
- Aiken vs. State Board of Health, 71.
- Air, moisture as an impurity in, 423.
- Air of the House of Representatives, 48.
- Air-passages, growths and foreign bodies in, 208; removal of growths and foreign bodies from, 211.
- Albuminuria in persons apparently healthy, 297; pathological conditions of, 420; puerperal, and convulsions, jaborandi in, 174, 196; treatment by inhalation of oxygen, 421.
- Alcohol question in England, 87.
- Alcohol, substitutes for, 155; in phthisis, 624.
- Alcoholic coma, diagnosis of, 168.
- Alcoholism and chloralism, 273.
- Alcoholism, chronic, treatment of, 312.
- Alimentation, supplementary rectal, 442.
- Allport, Dr. Frank, oxalate of cerium in chronic cough, 69; grindelia robusta in asthmatic affections, 594.
- Alopecia, 326.
- Alteration of prescriptions, 230.
- American Association for the Cure of Inebriates, 432, 492, 570.
- American Gynecological Society, notice of transactions of, 613.
- American Journal of Otolary, 168.
- American Medical Association, 384, 400, 467, 469, 475; report of sections of, 494, 518.
- American Neurological Association, 575.
- American Public Health Association, and National Academy of Sciences, 165; and the Withers bill, 212.
- American Surgical Society, 504.
- American Veterinary College, 263.
- Ammonia, intravenous injections of, 532.
- Amputation, avoidance of pain after, 120; through inflamed tissues, 445.
- Amyl nitrite as a cardiac stimulant, 414.
- Anæmia, progressive pernicious, changes in the sympathetic in, 373.
- Anæsthesia, local, 288; in ovariectomy, 549; produced in children by chloral, 192; rapid, 110.
- Analysis, elementary and quantitative, 256; of one thousand consecutive midwifery cases, 107.
- Anatomy, Chinese, 576; human, and evolution, 169.
- Aneurism of carotid and distal ligature, 384; of the palmar arch, 33; popliteal, treatment by Esmarch's bandage, 228; traumatic, of eyelid, 559.
- Angina pectoris, nitro-glycerine as a remedy for, 350.
- Animal heat, 515.
- Ankle-joint, resection of, 378.
- Annual Report of the New York Dispensary, 1879, notice of, 581.
- Anterior cornua, softening of, in recent myelitis, 252.
- Anterior splint, new modification of, 228.
- Anthropological study, 208.
- Antidote in carbolic acid poisoning, 262.
- Anti-emetic, "spirit of walnut," 128.
- Antiperiodic, new, 304.
- Antiseptic surgery, 206, 269, 356, 561.
- Antiseptic treatment of the genital canal in women, 554.
- Anus, effect of constipation on, 539.
- Aorta, aneurism of arch of, 305.
- Aortic insufficiency, development of, in a case of acute rheumatism, treated by salicylic acid, 61.
- Aphasia, cerebellar lesion with, 251; due to thrombosis of small twigs supplying the speech region, 425; sudden development of, case, 260.
- Apomorphia in cyanotic, 405.
- Appendix vermiformis, perforation of, by tubercular ulcers, 228; pin in, 3.
- Archives of Medicine, 240.
- Arkansas State Medical Society, 551, 583.
- Arsenic in green leather, 153.
- Arsenical poisoning and green eye-shade, 192; dialyzed iron in, 192.
- Arsenite of soda, antidote for, 47.
- Arteries, novel distribution of, at the base of the skull, 379.
- Articular ost'itis, 187.

- ...atism, 166, 394; lectures on, 32,
 treatment of, 213.
 ...paralysis, acute, 85.
 Dr. John, notice of book by, 231.
 ...in the new-born, 205.
 ...ation in the treatment of perityphlitic abscess, 371;
 in abscess of liver, 176; successful, of abscess of
 kidney, 251.
 Asthenopia, 377.
 Asthma millari, case of, 153.
 Astigmatism, 143.
 Asylums, overcrowded, 181.
 Asymmetry of the brain, 376.
 Athetosis, 330; case of, 441.
 Atkinson, Dr. Wm. B., notice of book by, 231.
 Atlas in two segments, 91.
 Atrophy of brain, congenital absence of hand with, 251.
 Atrophy, progressive muscular, 506.
 Atropia in ophthalmic practice, 492; in pyæmic chills,
 204; and eserine, 448.
 Athill, Dr. Lombe, 168; notice of book by, 328.
 Austrian universities, 479.
 Aural hygiene and the public schools, 254.
 Autophony and tinnitus aurium, causes of, 128.
 Aveling, Dr. J. H., notice of book by, 329.
- B.
- Bacteria in carbuncle, 192; utilization of, 144.
 Baldness, treatment of, 144.
 Baudage, elastic, in the treatment of aneurism, 179;
 solid rubber, in surgery, 319.
 Barker, Dr. Forlyce, on jaborandi, or pilocarpine in
 pnerperal albuminuria and convulsions, 196; treat-
 ment of hemorrhage during abortion, 232.
 Barry, Dr. R. A., reply to "Nonne," 550.
 Bartholow, Dr. Roberts, 311.
 Battey's operation, 106.
 Bayles, Dr. Geo., sedative action of calomel, 454.
 Beach, Dr. A. P., a giant birth, 271.
 Beard, Dr. Geo. M., on differential diagnosis of neuras-
 thenia, 181; electrolysis in surgery, 114; on nervous
 diseases connected with the male genital function,
 73, 555; on writer's cramp and allied affections,
 244.
 Bell, F. Jeffrey, notice of translation by, 280.
 Bellevue Hospital, reports, 105, 250, 348, 394, 514, 536.
 Bellevue Hospital Medical College, 239, 528.
 Bennett, Dr. J. H., notice of book by, 329.
 Beribéri, a case of, 397.
 Bert, M. Paul, 143.
 Biddle, Dr. John Barclay, obituary of, 94; resolutions
 on death of, 119.
 Bigelow, Dr. Horatio R., on loss of memory in cerebral
 softening, 319; neuritis, 574.
 Bigelow, Dr. Henry J., litholapaxy, 593.
 Bigelow, Jacob, M.D., LL.D., obituary of, 167.
 Bigelow's method, lithotripsy, 259.
 Billings, Dr. John S., Index Catalogue of the National
 Medical Library--the new health bill, 260.
 Bismuth in onychia maligna, 397.
 Black vomit, cause of, in yellow fever, 249.
 Blackwood, Dr. Wm. R. D., on the treatment of acute
 articular rheumatism, 213.
 Bladder, multiple abscess of, 355; treatment of rupture
 of, 421; irritable, 612.
 Blatta orientalis, action of, 263.
 Blepharitis, treatment by vulcanized india-rubber, 144.
 Blood-corpuscles, counting of, 491; do the colored pos-
 sess contractility? 331; has the red of the mamma-
 lian a nucleus? 112; variations in the number of
 human, 325.
 Blood, defibrinated, in rectal alimentation, 308; trans-
 fusion of, in opium-poisoning, 252; filaria in, 354.
 Board of health, a new, 490.
 Body-snatching, 119.
- Borek, Dr. Edward, notice of monograph by, 328.
 Bosworth, Dr. F. H., laryngeal phthisis, 484, 459.
 Botany, medical, 182.
 Bozeman, Dr. Nathan, anaesthesia in ovariotomy, 549;
 reply to Dr. Sims, 213.
 Brain, atrophy of, with congenital absence of hand, 251;
 sections of, 376; tumor of, 533.
 Bramblett, Dr. W. H., on cool acidulated water in cysti-
 tis, 141.
 Bright's disease, lecture on, 256; resina copaibæ in, 57;
 Mahomed on, 600.
 Bristol, Dr. B. J., on acute articular rheumatism, 166.
 British Medical Association, delegate to, 504, 600.
 Bronchial glands, diseases of, 107.
 Bronchitis, 111.
 Brooklyn Board of Health, control of contagious diseases
 by, 468.
 Brown, Dr. Thomas R., cases of urethral surgery, 199.
 Brown, Dr. Y. W., labor, with pendulous uterus, 359.
 Bryant, Thomas, F. R. C. S., notice of manual by, 283.
 Bucknill, Dr. John Charles, notice of book by, 65.
 Buried in a mine, 442.
 Burke, Dr. Martin, report of four cases of pyothorax,
 452.
 Burns, charcoal for, 264; deformity produced by, 211.
 Byford, Dr. Wm. H., 288.
 Byrne, Dr. John, 216.
- C.
- Cabell, Dr. J. L., on the American Public Health Asso-
 ciation and the Withers bill, 212.
 Caffein as a diuretic and cardiac stimulant, 226.
 Calcium sulphide and inflammation of the external audi-
 tory meatus, 552.
 Callender, Geo. W., F. R. S., 46; lecture on avoidance of
 pain in the dressing of surgical cases, etc., 25.
 Calomel, sedative action of, 453.
 Cancer of stomach, etc., 349; of rectum, lumbo-colotomy
 for, 185.
 Cannabis indica in epilepsy, 325.
 Canthoplasty, 377.
 Carbolic acid to abate pustulation of small-pox, 284.
 Carbolic acid poisoning, 373, 378; antidote in, 262.
 Carbolic acid spray in phthisis, 119.
 Carolina twins, 96.
 Carbolized jute, 59.
 Carbonic acid gas, 311; in intermittent fever, 204.
 Carbuncle, bacteria in, 192.
 Cardiac hypertrophy, cause of, 349.
 Care of the insane, 62.
 Carotid, aneurism of, and distal ligature, 384.
 Carroll, Dr. A. L., valvular lesions of the heart, 57.
 Castle, Dr. F. A., mortality of scarlatina among the
 tenement-house population, 574.
 Cat, frozen sections of, 311.
 Cataract extraction, 447, 491.
 Caulophyllum, 310, 402.
 Central Turkey College, 622.
 Centrum ovale, 376.
 Cerebellar lesion, with hemiplegia and aphasia, 251.
 Cerebral apoplexy, treatment by injections of ergotine,
 144.
 Cerebral softening, loss of memory in, 319.
 Cerebral and spinal exhaustion, 465.
 Chaillé, Dr. S. E., on evolution and human anatomy,
 169.
 Chancre, perchloride of iron in, 312.
 Chapped hands, prescription for, 48.
 Charcoal for burns, 264.
 Charcot, J. M., notice of lecture by, 266, 280.
 Charity Hospital reports, 10, 47, 224.
 Chaulmoogra oil in leprosy, 312; in phthisis, 514.
 Chemist and Druggist, 576.
 Chenopodium, poisoning by oil of, 312.
 Chestnut bark as an antiperiodic, 304.
 Chicago Gynecological Society, 235.

- Chicago Medical Society, 111, 402, 451, 479, 527.
 Chills, pyæmic, atropia in, 204.
 Chloral anesthesia in children, 192.
 Chloral as a vesicant, 311.
 Chloral inebriety, 570.
 Chloral, oleaginous solutions of, 157.
 Chloralism and alcoholism, 273.
 Chlorate of potassa poisoning, 178.
 Chlorate of potassa, remedial and fatal effects of, 241.
 Chlorine, free, in treatment of diphtheria, 48.
 Chloroform and supra-orbital tie, 275; and tetanus, 143; as a uterine stimulant, 113.
 Cholagogues, 261.
 Cholecystotomy, 539, 592.
 Cholera infantum, 546; strawberries in, 143.
 Chorea, adult, 553; treatment of, 204.
 Chronic alcoholism, treatment of, 312.
 Chylous urine and filaria in blood, 354.
 Cinchona alkaloids, duty on, 516, 583.
 Ciniselli, Dr. Luigi, death of, 192.
 Circumcision for incontinence of urine, 394.
 Circulation, quinine and the cerebral, 539.
 Classen, Alexander, notice of book by, 256.
 Clavicle, fracture of, improved appliance, 261.
 Cleft palate, treatment of, 538.
 Cleborne, Dr. C. J., a double forceps, 95.
 Climate of Africa for consumptives, 252.
 Climate and diseases of Northern Dakota and Montana, 343.
 Club-foot, lectures on, 128; Syme's amputation for, in the adult, 491.
 Code of ethics, 312.
 Cod-liver oil, assimilation of, 204; emulsion, 312, 582.
 Colchicine, injections in ischias, 61.
 Coleman, Dr. John S., the metroclyst, or intra-uterine irrigator, 455.
 College of Physicians and Surgeons, 239, 528, 552.
 Colles's fracture, 180.
 Collodion, iodoformized, 238; in enlarged lymphatic glands, 212.
 Colon, partial excision of the descending, 275.
 Color blindness, 110, 548.
 Columbus Medical College, 598.
 Comparative pathology, 422.
 Compound hare-lip, 210.
 Conjunctiva, sarcoma of, 307.
 Conjunctivitis, 377.
 Connecticut Medical Society, 566.
 Constipation, effects by, on rectum and anus, 539; prescription for relief of, 402.
 Constitution of climate (Lente), 255.
 Consumption, climate of Africa in, 252.
 Contagiousness of phthisis, 227.
 Convention of American Medical Colleges, 215.
 Cook County Hospital, Chicago, reports, 33, 71.
 Copaiba resins and Bright's disease, 57.
 Cornea, foreign bodies in, 377.
 Corson, Dr. Thomas J., obituary notice of, 479.
 Coryza, eucalyptus globulus in, 212.
 Cotton-wool dressing in Paris hospitals, 178.
 Cough, Fothergill's mixture for, 203.
 Cowling, Dr. R. O., 499.
 Cracked nipples, treatment of, 143.
 Cranioclast, Wallace's, 288.
 Cranium, compound punctured wound of, case, 233.
 Creasotic glycerine in ulcers of cervix uteri, 263.
 Cremation, 384; novel view of the question, 69; societies, 424.
 Creveling, Dr. J. P., 215.
 Crook, Dr. John Taylor, 551.
 Group, membranous, and diphtheria, 12, 540.
 Currie, Dr. D. A., a double canulated needle, 406.
 Curved flap in plastic operation on the face, 82.
 Cushman, Dr. Elizabeth M., on puerperal albuminuria treated by jaborandi, 154.
 Cyanide of potassium, poisoning by, 576.
 Cynanche, apomorphia in, 405.
 Cystitis and acidulated water, 46, 141.
 Cystitis, acute, in women, new method of treatment, 560; milk diet in, 143; chronic, 107; artificial vesico-vaginal fistula in, 273.
- D.
- Da Costa, Dr. J. M., clinical lecture, 313.
 Darby, Dr. John Thomsen, obituary of, 574.
 Death, causes of, in surgical operations, 605.
 Death-rate in Russia, 407.
 Deformities, rachitic, osteotomy for the correction of, 392.
 Deformity of nose, 389.
 Deformity produced by a burn, 211.
 Delirium tremens, treatment of, 204.
 Deleuze, J. P. F., notice of book by, 581.
 Dentists in Holland, 552.
 Derby, Dr. Richard H., a peculiar form of corneal opacity, 415.
 Dextro-quinine as an antiperiodic, 609.
 Diabetes, 301; complicated by gangrene of the plantar region, 420.
 Dialyzed iron in arsenic-poisoning, 192; hæmatinic properties of, 490.
 Diaphragm, acute rheumatism of, 61.
 Diastased iron, 408.
 Dichloride of ethylene, new anæsthetic, 226.
 Diphtheria and acute leucocythæmia, 539; and membranous croup, 12, 540.
 Diphtheria, treatment of, 72, 324; free chlorine in, 48; sulphur in, 515.
 Diseases, prevailing, of 1879, 488.
 Doctors in France, 463.
 Double hearing, causes of, 128.
 Double forceps, 95.
 Dowse, Dr. Thomas Stretch, notice of book by, 580.
 Drainage, improved method of, in empyema, 346.
 Dropsy, tubal, 355.
 Drowned, resuscitating the apparently, 72.
 Drunkenness, habitual, cure of, 236.
 Dry suture, 119.
 Duboisine, the action of, 273; as a mydriatic, 515; in ophthalmic practice, 402.
 Duncau, Dr. Wm. F., on naso-pharyngeal catarrh, 77.
 Duodenitis, 514.
 Duodenum, perforating ulcer of, 188.
 Durant, Dr. Ghislandi, notice of book by, 40.
 Duty on cinchona alkaloids, 516, 583.
 Dwight inquest, 501.
 Dysentery, abscess of liver following, 176.
 Dispensary, the National, notice of, 562.
 Dyspepsia, salicylic acid in, 576.
- E.
- Ear disease and sewer-gas, 359.
 Earth treatment of tumors, 491.
 Eccentric genuclast, 247.
 Electricity and exudation of mercury from the skin, 621.
 Electric light in the coal-mines, 110.
 Electrolysis, permanent removal of hair by, 270; in surgery, 114.
 Elephant, pregnancy in, 287.
 Elephantiasis arabum, lymphatic, 85.
 Eliot, Dr. Ellsworth, reinterment of the remains of John Hunter, 80.
 Ellis, Dr. Edward, notice of book by, 280.
 Elsberg, Dr. Louis, on contractility of colored blood-corpuscles, 331.
 Ely, Dr. W. S., improved method of drainage in empyema, 346; contracted kidney, 116.
 Embryology, 169.
 Emmet, Dr. T. Addis, notice of book by, 511.
 Empyema, pulmonary, 394; compensatory in acute thoracic diseases, 60.

- Empyema**, 536; aspiration and open incision without injections, 594; in child two years old, 349; improved method of drainage in, 346; treated by open incision without injections, 321.
- Emulsion**, cod-liver oil, 582.
- Encephalous sarcoma**, general, 306.
- Engineer**, The Plumber and Sanitary, 620.
- Enterocoele**, vaginal, 107.
- Epidemics**, prevention of, 494; of 1879, 488.
- Epidermal cells**, peculiar alteration of, 34.
- Epiglottitis**, section of, 609.
- Epilepsy**, lecture on, 529; *cannabis indica* in, 325; syphilitic, 252; trephining in, 85.
- Episcopal Hospital**, Philadelphia, reports, 203.
- Epistaxis** and ergotine, 312.
- Epithelioma**, *Thuja occidentalis* in, 59; in Kashmir, 301.

EXOPHTHALMIC GOITRE OCCURRING IN A CHILD, AND FOLLOWED BY ST. VITUS' DANCE.

A CLINICAL LECTURE DELIVERED IN BELLEVUE HOSPITAL.

By A. JACOBI, M.D.,

CLINICAL PROFESSOR OF DISEASES OF CHILDREN IN THE COLLEGE OF PHYSICIANS AND SURGEONS IN THE CITY OF NEW YORK.

(Reported for THE MEDICAL RECORD.)

GENTLEMEN:—The history of the case before us is as follows: Hattie Wagner, aged thirteen years, and a native of the United States, was admitted to the hospital on the 25th of January, 1879. Her father, *et.* 58, is living, and in good health. Her mother, *et.* 40, is living, but has never been a strong woman. She has always been nervous and anæmic, and has had four dead and eight living children. Our patient has always been what is commonly called "a delicate child." She has had two falls, and both times she struck upon her head; the first occurred when she was *five*, and the second when she was *seven* years old. Her mental condition has been fair. Some years ago she had exophthalmic goitre, for which she was treated at the Mt. Sinai Hospital. On December 30, 1878, she had an attack of pain in her right shoulder, and soon after lost the use of her right hand and leg. She had been attending upon her sick mother, and had not taken much food for several days immediately preceding the attack. On admission, it was noticed that there was some swelling of the thyroid gland, the left lobe being most prominent. The action of the heart was irregular; no valvular murmurs were found. The lungs appeared to be normal. Her gait was characteristic of well-marked chorea, and the choreic movements were almost continuous. When asleep the movements are usually suspended, but not invariably. She was put upon the use of iron. On February 8th she suffered considerably from headache, and bromide of potassium was ordered. On March 1st she had not had headache for some time, and the chorea was improving.

The case before us is the twelfth, occurring in children, which has been recorded in medical literature. Three of the eleven, previously related, are my own, and have been published in the June number, 1875, of the *American Journal of Obstetrics and Diseases of Women and Children*. The scarcity of the cases and the interest connected with them will be an excuse for a recital of their histories in this connection. Mary S., Bolton, Lake George, came under my observation in the summer of 1874, during my residence in the neighborhood of that village. She was then ten years old, and had suffered from her symptoms "for years." She was of average size; well developed, pale, intellectual; a good scholar, a poor eater. Now and then her face and her feet would swell. The functions of her rectum and bladder were normal. She complained of great weakness; could not walk without an effort; the heart would beat violently; and dysp-

nea set in on slight exertion. The dulness over her heart was too extensive by one-half; the shock perceptible to both hand and eye from the third to the sixth intercostal spaces. A loud systolic murmur was audible all over the chest, covering the diastole. It was of equal strength over mitral and aortic regions, and extended into the carotids. The radial pulse was feebler than normal. There was no history of any disease except malaria; no rheumatism. No swelling of the neck, no affection of the eye was noticed at that one visit she paid me; at all events, it must have been very slight, if it was present at all. Lungs were normal; nor could anything abnormal be discovered in her abdominal viscera. Under the circumstances my diagnosis was that of a general chronic endocarditis, and the prognosis a very grave one. For a long time, during the following autumn and winter, she took iron and digitaline, and followed such dietetic rules as I saw fit to give. She called upon me again the day I left that part of the country, in the early part of September, 1875. To my astonishment she was better to all appearances in her general health than the previous year. She could walk better, and her appetite had improved. The local symptoms were the same everywhere. The size of the heart was perhaps a little less; the murmur as loud and extensive as last year. Besides, I noticed at once a slight protrusion and immobility of her eyeballs, a staring look, and somewhat swelled lower eyelids, and a considerable goitre. The diagnosis was changed into that of Graves's disease, and the prognosis corrected accordingly. Three months she took tinct. ferri and digitalis regularly, and when, in January, 1876, I received her news, they were favorable. Since that time she has been treated now and then, but she has not outgrown her hydræmia and some slight cardiac murmur to this very day.

Dr. Moeller, of West Thirty-seventh street, introduced to me a little patient of nine years, Louisa W., whom he had attended for several months, a few years ago. When presented to me she was greatly improved already. Still she was anæmic, and of small stature; smart, and a good scholar. The contractions of her heart were both visible and palpable over three intercostal spaces—the pulsations of both carotids unusually distinct. The systolic murmur was strong and audible over the whole chest, both anteriorly and posteriorly. Her eyes did *not* protrude. The thyroid gland was slightly swollen on the left side; very much so, and protruding, on the right. It was not the first time, however, that I noticed a unilateral swelling of the thyroid gland in Graves's disease. She had steadily improved under the use of iron and digitaline (gr. $\frac{1}{10}$ daily) and quinia, and roborant diet, and thus the treatment was continued. When I saw her four months afterward, her general appearance was about normal; still the child was small, her eyes did not protrude, her goitre was not visible to the left of the median line, and less marked than formerly on the right; her heart's action was less impetuous, and the murmur less loud and less extensive. Of her complete recovery I entertained no doubt.

The third case is an exact counterpart of the one just mentioned. She was a patient of the clinic, and its records contain the few notes which were taken at

her two visits. She was nine years old, of average size, not remarkably anæmic. Heart loud and impetuous; systolic murmurs very strong and extensive; eyes not protruding; the right lobe of the thyroid considerably, the left but slightly swelled. Nothing was known about a previous disease, nor was there any discoverable at the time of our examination. A similar treatment was resorted to, with what effect we have had no means to ascertain since.

The main symptoms of the disease, when found in children, are the same as reported by Flajani, Parre, and Adelman, and finally appreciated in their full value by Graves and Basedow. It is well known to you that the complex symptoms are palpitation and enlargement of the heart, swelling of the thyroid gland, and protuberance of the eye. In most of the cases all the symptoms are present; in some, one or the other may be absent. Particularly is that the case with regard to the swelling of the thyroid gland and the exophthalmos: the latter perhaps more so than the former. In fact, in a number of cases of children affected with the disease, the latter was either absent, or but imperfectly developed. The area of dulness on percussion over the heart is considerably enlarged. Its shock is seen over two or three, sometimes more, intercostal spaces. It is not always very strong, but distinctly visible. There are murmurs all over the heart, and over a greater portion of the large arteries and veins. Both arteries, and particularly veins, are found dilated. Even the arteries of the retina have been found enlarged. The pulse is very frequent—120, 150, 180, and even more. The palpitation of the heart and the corresponding dyspœna, is a very serious and constant complaint on the part of the patient. The circulation is suffering all over the system. There is sometimes œdematous swelling of the hands and feet. There is dizziness and great irritability. The complexion of the patients, who are mostly very anæmic, is generally pale and sallow, and changes very frequently. The face suddenly flushes, is now and then covered with perspiration; so with other parts of the body. Ebstein reports a case of unilateral hyperidrosis; and similar observations have been made by other authors, such as Nitzelnadel and Chvostek. The temperature is generally not increased; but when the nervous excitement is very great a slight increase has sometimes been observed. Though the dilatation of the blood-vessels be very general, the spleen has, as a rule, not been found enlarged. Nor have there been found the so-called *taches cérébrales* of Trousseau, which are so commonly found in meningitis, sometimes also in typhoid fever, or toward the fatal termination of other serious diseases, and mean nothing else but vaso-motor paralysis. The swelling of the thyroid gland will sometimes be seen at an early stage of the disease, and its increase in a number of cases is very rapid. Sometimes it takes a long time, however, before it is fully developed. Its condition is not always the same. It may be painful or painless; soft or hard; compressible or not. It may be unilateral or bilateral; it may be changed within a very short time, or remain unchanged for a long time. In fact, the gland may never return to its original size. When unilateral, it appears the right lobe is more frequently swollen than the left. There are but few cases, however, in which but one lobe was affected through the entire course of the disease.

The last symptom in the series enumerated is always the exophthalmos. It may be very slight. Sometimes its only symptom will be a certain stare on the part of the patient. Sometimes, however, the eye protrudes to such an extent that it appears very

large, indeed, a large portion of the sclerótica being visible outside the eyelids, which either close over the eye with great difficulty, or not at all. In consequence of this disproportion between eyelids and eye, the movement of the eyelids is retarded, and very slow indeed—a symptom which Graefe considered pathognomonic of the disease. In those cases in which the cornea is not sufficiently covered by the eyelids, and the movement of the latter is interfered with, the cornea is apt to suffer, and in not a few instances in which the disease has occurred in adults, destruction of the cornea has taken place in consequence. No such case, however, has been observed among children.

All the symptoms enumerated can be traced back to the disorders of the vaso-motor system, the sympathetic, and principally to its cervical portion. In fact, a number of anatomical changes have been found in the upper cervical ganglion in such cases. Still the number of post-mortem examinations has been but limited. The changes which have been found have either been proliferations of connective tissue, such as found by Lancereaux in the left ganglion inferius colli; or gray infiltration, such as reported by Reid in the middle and lower cervical ganglion; or enlargement and thickening of the cervical sympathetic, as found by Virchow. But when we come to sift the symptoms, it appears, from the knowledge we have of the physiological functions of the sympathetic, that there is apparent discrepancy. The large blood-vessels of the neck and the head are considerably enlarged—a symptom which we have been in the habit of attributing to vaso-motor paralysis. The symptoms belonging to the heart can be best explained by irritation of the sympathetic, and also those belonging to the unstriated muscles in the orbit and the eyelids. This discrepancy, however, is explained away, and, it appears to me, very satisfactorily, by the discoveries of Goltz and others, who find that the dilatation of blood-vessels may be due to vaso-motor paralysis, but is due, in many cases, to the irritation of sets of fibres of the sympathetic, which, when stimulated, will dilate blood-vessels. In this manner all the symptoms, those belonging to the eye, the thyroid gland, and the heart, would be best explained by taking them as the result of irritation of the sympathetic. The majority of cases which have been observed belong to adult women. In most of them this affection was not the only disease noticeable among them. Their history was one of previous disorganization of the nervous system. Many of them were anæmic from childhood, and suffered from disturbances of menstruation. A few whom I remember had suffered from St. Vitus' dance when children. Many had suffered long from trifacial neuralgia, from intercostal neuralgia, from hysterical symptoms of all kinds, and, finally, the symptoms of Graves' disease would develop themselves. There have also been complications with intellectual disorder. In a few cases there were mania, melancholia, and epilepsy. Chlorosis has existed in a great many cases. Some were able to trace their disease back to emotional excitement, to sudden fright, or to traumatic injury of the head. In a very few cases—thus in the case reported by Solbrig, a boy of eight years—the mother had suffered from a similar affection. Thus the impression would be, even if there were no proofs, that the disease is not only intimately connected with nervous disorders, but is a nervous disorder itself, an impression more than fortified, even verified by anatomical changes found in post-mortem examinations and the physiological explanation of all the symptoms. The case before us is peculiar, in that it has gotten nearly well, with the

exception of a moderate amount of swelling of the thyroid gland, which is pretty hard, and not compressible. There is hardly any symptom left which can be traced back to the original disease—that is, with the exception of the chronic enlargement of the thyroid gland, but she must be considered well of her exophthalmic goitre. She is so well that there are not even cardiac murmurs, neither organic nor functional, and certainly there is no exophthalmos visible at this time. In this condition it appears she has been for a year or two. No serious disorder has been noticed in her heart. To what extent her intellect or temper have suffered from her general disposition or from her sickness we are certainly not able to state, but there is a serious affection now present which, though it has not been observed very frequently, must still be brought into some connection with her original sickness. Two cases of Gagnon exhibited the very same complication which we notice here—that with *chorea minor*. In those cases also the exophthalmic goitre was the first affection, and was then followed by St. Vitus' dance. Our case exhibits none of the symptoms that we are apt to find in a large number of cases of *chorea minor*. There are no cardiac murmurs, there is no pain in the head or vertebral column, neither spontaneous nor upon pressure, which we meet with so very frequently. Thus it is to be taken as a simple neurosis, the cause of which is certainly unknown to us.

Without intending to go further into the principles of the pathology of the disease, I have to point to a few facts which it is well to emphasize once more. This child has got nearly well of her exophthalmic goitre. Heart and eye are normal. There is enlargement of the thyroid gland, which, as all the other symptoms have disappeared some time ago, will probably prove permanent unless relieved by proper treatment. It is now years since the disease commenced; and it may take years before the goitre will entirely disappear, if at all. If it does, the whole sickness will run a course perhaps of six or eight years—a not uncommon thing, when we remember such cases as, after lasting a half-dozen or a dozen years, would never get entirely well. On the other hand, it is worth while to remember that some of the cases reported have got well in a proportionately short time. Solbrig's case is, it is true, an exception; but it was so acute in its beginning and in its course, that ten days were sufficient for the disease to show its first decided symptoms, and disappear. The rule is, that the patients suffer long, and recover but partially. The percentage of complete recoveries is but small. Twenty-five per cent. have recovered completely. As far as children are concerned, it appears that most of them have not been so sick as many adults; and partial recoveries have, at all events, been accomplished in shorter time than amongst adults.

If the pathology of the disease is such as I have stated, the indications for treatment are simple enough. The results, as you have seen from the remarks made on the long duration of the sickness, and the small percentage of complete recoveries, are indeed not very encouraging. We have to deal with irritation of the sympathetic nerve, with dilatation of blood-vessels, with a general neurotic condition, with deficient power of resistance, with anemia, etc. Thus there are indications with regard to the general condition of the patients, and in regard to the direct treatment of the disease. As far as local treatment of the sympathetic ganglia of the neck is concerned, galvanism has been resorted to as one of the principal, perhaps as the main, remedies. It has been expected that it

would, when directly applied to the ganglion of the neck, result in diminishing the size of the blood-vessels and the circulation about the heart, the neck, and the head. A great many cures have been reported; but it has always appeared to me that the novelty of the remedy had a great deal to do with the large number of speedy and absolute recoveries boasted of.

In general, it must not be forgotten that the application of the galvanic current to the deep tissues, and more still to a small point, has its great difficulties. The permeability to the electrical current, on the part of the tissues, differs greatly; and thus it is not in our power to limit the course of the galvanic current in certain directions. At all events, a portion of the galvanic current is lost. Moreover, a number of tissues and organs are influenced in the neighborhood of the point we aim at, and thus the effect, if not counteracted, is modified. I have always doubted whether galvanization of the sympathetic, by applying one electrode to the nape of the neck, and one directly to the ganglion by pressing down along the sterno-cleido-mastoid muscle, was as certain as it has been represented to be.

I can imagine that, in lean persons, and with a small electrode, the object can be accomplished to a certain extent, but to a certain extent only. It is impossible that an effect should be accomplished without, at the same time, affecting the pneumogastric nerve, which is in the immediate neighborhood, and which, so far as effect upon the heart is concerned, is directly antagonistic to the effect upon the sympathetic ganglia controlling the heart. I can therefore imagine that the irritation of the sympathetic is directly counteracted by irritation of the pneumogastric, both of them being reached by the same galvanic current. That I do not stand alone in this opinion has been proved in an essay by G. Fischer in the *Deutsch. Archiv für klin. Med.*, Vol. XX., p. 175.

As, however, this point is not absolutely settled, it behooves us to defer our final judgment until the cases are more numerous. Certainly, if a large number of cases have been, or will have been, reported, we are justified in relying upon a remedy, although we do not know much about its *modus operandi*. If the irritation of the sympathetic nerve is the cause of the disease, it is very much more probable that the sedative effect of the galvanic current is the one to be relied upon, than that we should have to fall back upon its irritant effect. If that be so, very probably the frequent application for a short time—a few minutes only—will be more indicated than an application once or twice in the twenty-four hours. In connection with this theory and advice, the number of cases in which the bromides have given relief are explained by the sedative effect produced by the remedy. It is not at all necessary to fall back upon the potassium, with its effect upon the heart. Very probably its effect is due to the bromine in the combination. The theory according to which an irritation of the sympathetic is the cause of the disease explains best the success—at least, partial success—which digitalis has given in a number of cases, especially that of Solbrig, and in a few of my own. By acting as a stimulant on the pneumogastric nerve, it would relieve the symptoms brought about by irritation of the sympathetic. In a majority of cases I have seen, not only in children, but in adults, there has been a decided amelioration of symptoms under the use of digitalis. Digitalis will act pleasantly in the same degree as belladonna would act unfavorably. I add this remark at once, because belladonna, or its alkaloid atropia, have been so frequently administered in a number of neurotic affections.

Of nerve specifics, I know of but one that has acted favorably in a few of my cases, and that is *arsenic*. As a rule, it is well tolerated. Its effect upon the digestive organs has not been remarkably unfavorable. On the contrary, it appears that it improves nutrition in neurotic persons suffering from anæmia, and a low standard of assimilation. It is always worth while to try it, either as Fowler's solution, or better as arsenious acid, and better still in the shape of Pearson's solution of the arseniate of soda, for a successive period of weeks, sometimes of months.

Ergot has been resorted to in a number of my cases. Its effect upon the size of blood-vessels, no matter what its original effect may be upon the nerve matter, has always encouraged me in administering it in such cases, and I feel positive, without being able to explain the action in every instance, that I have seen good results follow its use. The same I can say of quinine. Not unfrequently, therefore, have I combined ergot and digitalis, or ergot and quinine, or ergot, quinine, and digitalis, and believe that the combination of two or of all three has yielded good results. So far as ergot is concerned, it is desirable to begin with small doses. Even mild preparations, such as the fluid extract, sometimes are not well tolerated, and it will be necessary to discontinue them and use ergotine, either Bonjean or Squibb's instead. Very frequently, almost uniformly, when the former was not well tolerated, the ergotine in the form of pills and in the combinations enumerated above, was well borne and was successful. The constitutional debility in such cases will, as a rule, bear iron very well indeed. But sometimes it is tolerated only when the vascularity and irritability has partly disappeared; while these are very high it is better not to give it at all; arsenic is certainly generally better than iron. When the frequency of pulse has been diminished to a certain extent, when the flushing has disappeared, and when the local and general perspiration has, at all events, been reduced, and the palpitations are less, the time for the administration of iron has arrived, and until that time other restoratives are indicated rather than iron. When the symptoms are greatly modified, and the swelling of the thyroid gland remains, the preparation of iron to be used is the iodide, and the syrup of the iodide of iron is a mild form of administering it. It is well tolerated by the digestive organs, and any tendency to decomposition or fermentation on the part of the contents of the stomach is, to a certain extent, counteracted by the iodine developed by the decomposition of the preparation. Not infrequently in adults, and also in children, will the syrup of the iodide of iron suffice both as a stomachic and as a restorative. When, as you see it here, there is permanent swelling of the thyroid gland, not so much due to dilatation of blood-vessels as to induration resulting from cellular tissue hyperplasia, the iodides are indicated. As our patient here is anæmic, I do not propose to give her the iodide of potassium, but the iodide of iron. I believe that local treatment with the tincture of iodine, or the application, twice a day, of iodoform in colloidum (1:15), will certainly do good. I should also propose to allow a mild galvanic current to be applied to the tumor for its electrolytic effect, six or eight minutes, once or twice daily.

"SYPHILIS OF THE BRAIN AND SPINAL CORD," a series of lectures, which appeared in *The Medical Press and Circular*, have been published for the author, Dr. Stretch Dowse, by Baillière, Tindall & Cox, of London. Much matter and several colored plates have been added to this reprint.

CAUSES OF DEATH IN SURGICAL OPERATIONS.

By A. L. RANNEY, M.D.,

ADJUNCT PROFESSOR OF ANATOMY, IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK.

PART II.

AIR IN THE VEINS.

Etiology.—This distressing accident has always occurred, as far as my research has extended, in operations about the head, neck, or axilla.

Experiments on animals—by Morgagni, Valsalva, Bichat, and Nysten—have shown death to arise in the dog from an injection of three cubic inches of air into the jugular vein, and in the horse from three ordinary human expirations.

Bichat, in his experiments, concluded that even *one bubble* might result in death; but his associate investigators—Bell, Magendie, Amussat, Cormack, Wattman, Nysten, and Erichsen—do not verify such a conclusion.

Death seems to depend not only upon the amount of air introduced, but the rapidity of the injection seems also greatly to influence it.

In surgery, however, we have only to deal with the *spontaneous* admission of air into venous cavities, dependent upon a thoracic vacuum existing both within the pleuritic and pericardial sacs, and occurring during the act of inspiration.

Pathology.—There has been much discussion and many theories as to the exact physiological condition produced by the entrance of air into veins and the mechanism of its action as a cause of death.

Bell's theory argued that death was the direct result of *air upon the medulla oblongata*.

Cormack ascribes death to *dilatation of the right heart* alone, without abnormal valvular or pulmonary conditions.

Erichsen denies both of these conclusions, and claims that death results from *obstruction in the pulmonary capillaries* from the frothy condition of the blood, which resists the vis-a-tergo of the heart.

This theory has had great support; is based upon extensive experiments and pathological research; and, where small quantities of air enter veins, probably is correct.

Moore, however, in his paper on this subject, advocates an explanation, in which the *valvular* element is brought out as the most important factor, and which certainly merits attention.

He states his explanation briefly as follows: 1. Air, on entering the right ventricle, fails to close the wet tricuspid valve during the ventricular systole, from its light density and compressibility. 2. During the following diastole of the heart the air enters, or rather floats, into the pulmonary artery. 3. During the second ventricular systole the wet *pulmonary* valves also fail to close, and adhere to the sides of the vessel. 4. The succeeding diastole now draws into the ventricle blood from both the auricle and the lungs. 5. The cardiac systole now returns the blood again to its original situation, as both the tricuspid and pulmonary valves are open, and thus the circulation becomes arrested.

These two latter explanations probably cover the mechanism of death; the former being the most plausi-

ble when the amount of air in the heart cavities is small, the latter when a large quantity of air suddenly is introduced.

History.—In 1818 Beauchesne reported the first case of this accident occurring during the removal of a tumor of the right shoulder, the internal jugular vein being wounded. The patient lived fifteen minutes.

Subsequently cases were reported by Dupuytren, Delpech, Castara, Roux, Ulrick, Mirault, Warren, Mott, Malgaigne, Bégin, Erichsen, Cooper, Clemot, and others. Some of those recovered; some met almost instant death; some died of pneumonia from bronchial irritation at a later date.

In all of these cases, however, an abnormal condition of the opened vein existed, characterized by a failure to collapse, termed by the French *canalization*.

This abnormal condition may be produced either *artificially* or by some *anatomical* changes.

A. *Artificial canalization* may result from one of four conditions, viz.: 1. Tension of the aponeuroses, holding the mouth of a vein open. 2. Veins opened by platysma contraction. 3. Traction on the pedicle of a tumor. 4. Vein at an angle of the wound opened by traction on the flaps.

B. *The abnormal anatomical conditions* producing canalization are: 1. Indurated cellular investments about the vein. 2. Induration, or inflammatory thickening of the venous coats.

Thus in Beauchesne's case traction existed; in Delpech's, hypertrophy of axillary vein; in Castara's, section occurred during traction; in Roux's, section occurred during traction; in Ulrick's, the vein was enclosed in a tumor; in Mirault's, the vein was enclosed in a tumor; in Warren's, tension from position of arm existed; in Mott's, the *facial vein* was tense from position of the head; in Malgaigne's, the vein was enclosed in the tumor; in Bégin's, the jugular vein was tense from traction.

Symptoms.—When air is allowed to enter into the veins of a dog by section, there occurs: 1. A hissing noise, with gurgling at the mouth of the vein. 2. Struggles during the subsequent inspirations. 3. A churning noise at the apex of the heart during the ventricular systole, with a bubbling, thrilling, and rasping sensation on palpation. 4. The circulation becomes feeble, but the heart's action *remains forcible*. 5. The animal becomes unable to stand, rolls over, utters a few plaintive cries, is convulsed, extrudes its feces and urine, and dies.

In man, however, there are additional symptoms given us by the *expressions* of the patient; thus the patient experiences terrible constriction in the thorax immediately after the air enters; screams, moans, and subsequently whines as the symptoms increase. The pulse early becomes imperceptible, the heart's action labored; convulsions come on rapidly, and death usually occurs. Still, in Mirault's case three or four hours elapsed before death; in Clemot's, several hours; in Beauchesne's, fifteen minutes; in Roux's and Malgaigne's, death from pneumonia ensued; while in Erichsen's and Cooper's cases, recovery took place.

Treatment.—As *prevention* of this accident is of vital importance, the following suggestions may be of value: 1. Always close the mouth of any *open* vessel *instantly*, both on the proximal and distal end, and compress every vein before cutting it. 2. Avoid raising *any tumor* on the shoulder in operations about the neck, head, or axilla, without protecting the large veins by pressure. 3. Compress, between the wound and thorax, if fear exists, during alterations in the position of patient or tumor. 4. Bandage the chest

and abdomen tightly to prevent *gaspings respirations*, which tend greatly towards this accident.

As to the plan of *actual treatment*, after the accident has occurred, many suggestions have been offered, though their value will depend somewhat on the views held as to the mechanism of death. Thus Moore advises a *supine* position, to allow the blood to fall to the *back* part of the heart, and thus raise the tricuspid valves. Others advise the head low and the feet high, to relieve the anemia of the medulla. Mercier suggests *compression* of the *femorals*, *axillaries*, and abdominal aorta, for the same object; but this is objected to by others on account of the necessity of venous return, which is retarded by this method. Warren advises either *bleeding* from the temporal artery, *tracheotomy*, or *stimulants*, as the indications seem to demand, with galvanic shocks across the chest in case the heart's action seems to fail. Gerdy *compresses the chest*, hoping to expel or facilitate the passage of air through the lungs. In apparently fatal cases, Amussat and Blandin recommend *suction of air* from the heart, by means of a catheter passed into the open vein, or into right jugular if the former be impossible, with compression of chest at the same time. Magendie and Roux advocate suction alone. Reid and Cormack suggest the *opening of the right jugular vein* to relieve the right auricle.

Many of these plans have to me serious objections. Compression of the chest, after the accident has occurred, seems useless, and increases the pulmonary obstruction. Bleeding from the temporal artery depletes the already empty arteries. Tracheotomy only relieves a secondary symptom (dyspnea). Erichsen lays great stress on artificial inflation of the lungs to overcome the obstruction in the pulmonary capillaries, and suggests that mechanical respiration be kept up after this procedure, using at the same time ammonia to the nostrils.

Artificial respirations, with the *mouth* and *nostrils* closed, have been suggested as a remedial measure, the object being to expel air from the heart by the vein through which it entered. Finally, *injections of warm water* into the heart cavity, to render the valves movable, and subsequent artificial respiration to keep up the cardiac action, is resorted to, and recommended by Moore as a remedy in the severe type of cases. His steps for this operation are as follows: 1. Raise head during the injection, to allow air to escape through the fluid. 2. Open some vein in the neck, and evacuate its blood, to further assist the escape of air. 3. Avoid throwing in additional air with the syringe. 4. Inject with force enough to *fill*, but not *distend* the heart cavities. 5. To inject two ounces at a time, with velocity enough to raise the wet valves which are adherent to the walls of the heart. 6. To stimulate the heart's action, during the operation, by galvanism and artificial respiration.

Without pausing to elaborate these means of treatment, I pass now to the *third* source of death dependent on vessels, viz.: embolism and apoplexy.

EMBOLISM AND APOPLEXY.

By embolism we mean a plug in a vessel interfering with the circulation of the blood, and formed at a point more or less distant from the seat of obstruction; by apoplexy, the escape of blood from a vessel into the cerebral tissue. I have coupled the two, since cerebral embolism is the most common form in fatal cases, and because there are some marked points of similarity in the symptoms of *this form* and that of apoplectic extravasation. Both, if occurring during

a surgical operation, have been preceded by abnormal anatomical conditions, and owe their occurrence to the excitement of the operation, rather than to any act of the surgeon. Still, as these pathological conditions which previously exist may be determined, or suspected, before the date of the operation, the occurrence of either of these causes of death is not an absolutely unavoidable accident, and, in many cases, not undeserving of censure.

Etiology.—Embolism is usually caused by a former endocarditis, producing vegetations upon the valves, though it may result from a phlebitis, or from spontaneous coagulation of blood in small capillaries, from pressure of tumors, a pyæmic condition, and other causes; these plugs subsequently becoming movable. The former condition, viz., vegetations on the valves, is, however, the one most likely to produce abnormal cerebral conditions, as emboli from the venous system are seldom arrested till they pass through the right heart, and are mostly entrapped in the pulmonary organs.

Apoplexy, on the contrary, is not necessarily associated with heart lesions, but rather is produced by an atheromatous condition of the vessels, which exists as a result of a previous endarteritis from irritation of alcoholic blood and high living.

Symptoms.—The common symptoms of both of these conditions, when present, leading to error in diagnosis or treatment are chiefly: 1. Possible coma. 2. Paralysis. 3. Sudden death.

The distinctive symptoms between the two diseases, provided the attack is not immediately fatal, are best grouped as a differential diagnosis.

Apoplexy.

The attack, if serious, but not immediately fatal, is accompanied by coma and insensibility.

The indications of cerebral compression are present, as shown by the following symptoms:

The breathing is stertorous.

The face is flushed.
The pulse is full and slow.

The pupils are irregular. No aphasia exists (as a rule). The paralysis is slow in improvement.

The arteries are often felt to be atheromatous.

No cardiac lesion exists if the attack be uncomplicated.

A history of previous high living is usually present.

Embolism.

Under the same conditions consciousness is liable to be present during the attack.

The indications of cerebral anæmia exist, as shown by the following symptoms:

The respirations are normal (as a rule).

The face is pale.
The pulse is rapid and feeble.

The pupils are uniform. Aphasia is diagnostic. The paralysis usually improves slightly within twenty-four hours.

The arteries are normal.

The aortic and mitral valves are usually found to be abnormal.

A history of previous rheumatism and endocardial inflammation is generally detected.

Both may have been preceded by similar attacks; but in each a recurrence is liable to take place, even should no previous history of a former attack exist.

Treatment.—In severe cases of either of these conditions little can be done to relieve, save a symptomatic line of treatment. Cold to the head, venesection, and catharsis are usually employed in apoplexy, but more for the object of preventing further escape of blood than as curative measures. In embolism some improvement usually appears within twenty-four hours, without treatment, from a supply of blood, through the collateral circulation; but the prognosis depends greatly on the situation of the embolus, its size, and its character. Fatty degeneration often re-

moves the foreign body before degeneration of the brain occurs; and, in these cases, complete recovery may result.

We come now to the SECOND CLASS of causes of death, viz., "causes affecting the nervous system."

SHOCK AND COLLAPSE.

By the term "shock" is meant a state of body dependent upon a sudden or violent impression affecting some portion of the nervous system, and, through a nerve-centre, acting upon the heart. By "collapse," a state of extreme shock verging upon dissolution, but not resulting in immediate death. Life may be destroyed without pathological lesions, as in cases of sudden or violent blows upon the epigastrium, and as a result of powerful mental emotion; but these cases are uncommon, and are, as a rule, always preceded by one of the above-named conditions. It is to these two conditions (viz., shock and collapse), therefore, that I direct your attention as a cause of death during surgical operations.

Syncope is not to be confounded with collapse or shock, since it differs from them in three respects: 1. In its duration and degree. 2. In the mental condition of the patient and the acute sensibility of the special senses. 3. In its more rapid crisis, but less profound effects.

Collapse is divided, according to its symptoms, into three stages: 1. Stage of shock. 2. Stage of reaction. 3. Stage of excessive reaction.

This third stage has been described by Hunter as the "stage of irritability;" by some as the "stage of delirium;" by others as the "stage of inflammation;" and by Travers as the "stage of prostration with excitement."

Etiology.—The causes of collapse may be classified into

1st. *Injuries* involving a large amount of tissue or nerve trunks: Lacerations, burns, injuries to joints, injuries to organs, especially liver, testicle.

2d. *Poisons*, depressing the nervous condition: Tobacco, aconite, drastic cathartics, etc.

3d. *Shock to nerve-centres* resulting from blow on epigastrium, lightning, concussion of brain, mental emotions, excessive pain, sudden cessation of pain, cold douche.

4th. *Sudden and severe hemorrhage.*

5th. *Exhaustion*, as produced by excessive fatigue, excessive privation from food, prolonged suppuration, prolonged mental excitement.

There are also certain conditions which are predisposing towards collapse, such as "old age," "debility," prolonged anxiety, excessive fear, etc.

Pathology.—In fatal cases of collapse the pathological conditions are confined to the heart and circulatory apparatus; thus the heart cavities are usually found to be markedly distended; the right heart is engorged with blood; marked engorgements of the great veins and cavas exist; and imperfect coagulation of blood is present in the heart and large vessels.

Symptoms.—The symptoms of collapse differ with the various stages, and will be therefore separately enumerated.

The symptoms of the first stage (stage of shock) are: 1. Pallor of the whole surface of the body. 2. Bloodless lips. 3. A clammy moisture of the skin with drops of sweat on the forehead. 4. A countenance dull, shrunken, and contracted. 5. An eye deficient in lustre, and partially covered with the drooping lid. 6. Dilated nostrils. 7. A temperature depressed below normal. 8. Extreme muscular debility. 9. A pulse frequent and irregular, or feeble and often imperceptible.

ble. 10. Respirations short and feeble, or sometimes panting or gasping. 11. And finally, incomplete coma associated with nausea, hicough, vertigo, dimness of vision, and painfully acute hearing.

The symptoms of the second stage (stage of *reaction*) are: 1. Slow and gradual improvement in appearance of the face. 2. Improvement in the rhythm and the force of pulse. 3. Fuller respirations. 4. Sighing. 5. Return of power of deglutition. 6. Increase of temperature. 7. Change in the position of the patient from a supine posture (sign of debility) to the side. 8. Slight febrile action, followed by sleep, and often by convalescence.

This stage of reaction may not be uniformly progressive, but may be characterized by relapses and successive reactions. The prognosis depends on the rapidity of the stage of reaction.

The symptoms of the third stage, if present, are: 1. Dry heat of skin. 2. A rapid and bounding pulse, but always compressible. 3. Hurried but imperfect respiration. 4. Tremulous tongue. 5. Great thirst. 6. Restlessness and jactation. 7. Delirium (most marked at night). 8. Muscular twitchings.

As exhaustion comes on, the skin again becomes cold and clammy; the face pale and haggard; the pulse very rapid and fluttering; subsultus, coma, or convulsions usually precede death; death.

Treatment.—The treatment of collapse should be modified in two sets of cases. 1. Those associated with hemorrhage. 2. Those without hemorrhage.

In the first class of cases Travers makes the following suggestions as a summary of treatment. 1. Maintain a horizontal position. 2. Give brandy in *moderation* per stomach and rectum. 3. Apply hot flannels to the epigastrium and the extremities. 4. Early nourishment must be given following the use of stimulants. 5. The head should be kept cool to avoid mental excitement. 6. Early sleep, through opiates, should be obtained. Give hyoscyamus if opium fails to produce sleep. 7. If reaction be delayed beyond twelve hours, increase the stimulants, apply mustard to the epigastrium, and induce sleep through large doses of opiates.

C. T. Hunter, of Philadelphia, recommends placing patient in a bath at 98° and raising it rapidly to 110°. The respirations have thus been known to fall from 36 to 20.

Young recommends, in cases demanding serious operations, confinement of the patient, for one week previous to the operation, to the *same position* as required for the first week following the operation, in order to prevent the confinement becoming an exciting cause of shock.

In those cases not associated with hemorrhage the following treatment is suggested: 1. Opening of the external jugular vein, if distended, is advised, to relieve the distention of the right heart, since in experiments on animals this treatment has been proved efficacious. 2. Maintain the normal temperature of body if possible to do so. 3. Diffusible stimulants should be given with great care to avoid excessive reaction. 4. Artificial respiration should be used when demanded.

We now reach the third class of causes of death, viz.: "Causes affecting the blood."

ANÆSTHETICS.

The list of anæsthetics to-day in general surgical use comprises chloroform, sulphuric ether, nitrous oxide gas, bichloride of methylen, tetra chloride of carbon.

Preparations of amyl, although anæsthetics, are not used as general surgical aids, and the various prep-

arations employed for local anæsthesia do not enter into the cause of death, and are therefore omitted.

Effects of Inhalation.—All anæsthetics by inhalation follow, to a greater or less degree, a resemblance to the symptoms of chloroform and sulphuric ether.

In the first stage (that of *fauical* and *laryngeal irritation*) there is developed: 1. An increased flow of mucus. 2. A desire for air and sense of suffocation. 3. Frequent reflex acts of swallowing. 4. Coughing. 5. Struggles of the patient.

In the second stage (that of *general exhilaration*) we notice an increased pulse, increased respirations, flushing of the face, laughing, shouting, crying, and other symptoms of intoxication. The taste and smell are lost, and analgesia is present.

This stage is most prominent in the mercurial and hysterical temperaments.

In the third stage (the *tetanic* or *convulsive* stage), the muscles become rigid, the face cyanosed, the breathing arrested or stertorous, oposthotonos exists, and the eyes are staring and open.

This stage is least marked in women, and the feeble or debilitated.

In the fourth stage (the stage of *coma*) the surface becomes cool, diaphoresis is present, the countenance is placid, the pupils are normal or slightly contracted, the respirations become shallow but easy, and the pulse somewhat slower than normal.

CAUSES OF DEATH.

The causes of death in anæsthetics are: 1. Syncopal apnoea. 2. Epileptiform syncope. 3. Paralysis of respiratory muscles. 4. Cardiac paralysis. 5. Shock. 6. Coagulation of blood in the pulmonary capillaries. 7. Direct anæsthesia of lung tissue.

(A) **SYNCOPAL APNOEA** (so called by Richardson).—This cause of death occurs during the first stage of chloroform, *soon after administration of the anæsthetic is commenced*. It is explained by Richardson as due to "irritation of the peripheral nervous system associated with excess of carbonic acid in blood and arrest of heart's action," and by Bartholow, as due "to direct paralysis of the cardiac ganglia from contact with chloroform in the blood. These ganglia being in an abnormal state of susceptibility from causes not now understood."

(B) **EPILEPTIFORM SYNCOPÉ.**—This occurs during the *third* or *tetanic stage*. It is produced by tetanic fixation of the respiratory muscles, and interference with the pulmonary circulation, resulting in venous engorgement of right heart. Respiration in this form of death ceases before the heart's action is arrested.

(C) **PARALYSIS OF THE RESPIRATORY MUSCLES.**—This occurs during the stage of *complete muscular relaxation*. The heart beats for some seconds after respiration has ceased.

(D) **"CARDIAC PARALYSIS."**—This occurs during the stage of *complete insensibility* and analgesia. It is produced by paralysis of the cardiac motor ganglia. Respiration may continue for a short time after heart has ceased to act. J. Paget's case, 1857. Respiration seven minutes after heart failure.

(E) **SHOCK.**—This cause of death, when present, is induced by and combined with the respiratory or cardiac depression existing as the result of the anæsthetic. This may occur either in the early or late stages.

Faure's* theory attributes death from chloroform in all cases to coagulated or *thickened blood in pulmonary*

* Faure asserts that chloroform is never absorbed, but is always local in its action.

capillaries, from the direct action of too strong chloroform vapor.

Madden's* theory attributes death from chloroform to direct *anæsthesia of the lung tissue*, and therefore arrest of respiration and asphyxia.

The conditions rendering anæsthetics dangerous are: 1. Fatty degeneration of heart (a prominent contraindication). 2. Previous alcoholic history. 3. Brain tumors and degenerations. 4. Respiratory obstruction from swollen epiglottis, enlarged tonsils, œdema glottidis, laryngeal paralysis, thoracic tumors or aneurism. 5. Emphysema and obstructed pulse circulation, from engorgement of right heart, and deficient heart-power. 6. Valvular lesions, provided compensatory hypertrophy is not *proportionately* developed. 7. Incomplete anæsthesia during *painful* surgical procedures, causing death from shock, as the result of peripheral irritation.

Muscular debility and weakness from exhaustion, if otherwise uncomplicated, prove rather aids to anæsthesia than contraindications.

PREVENTIVE MEASURES AGAINST DANGER.—These may be comprised in the following rules: 1. A thorough examination—for sources of danger should always be made previous to administration of an anæsthetic. 2. Never administer on a full stomach, as anæsthesia of the glottis prevents expulsion of vomited matter from the larynx, in case it enters by regurgitation. 3. Never administer after long *fasting*, as absence of nutrition may tend toward cardiac paralysis. 4. Give one or two ounces of whiskey before administration. 5. Nussbaum (Berlin, 1863) suggests that a hypodermic dose of morphia be given before the administration of the anæsthetic; the results which he claims being (1) that it prolongs the anæsthesia, and (2) that less anæsthetic is required.† 6. Avoid all excitement to the patient from fear, sight of instruments, too many spectators, etc., all of which tend to induce shock. 7. Have appliances for resuscitation at hand, and plenty of fresh air during the administration of the anæsthetic. 8. In chloroform, mix only three and a half per cent. of the vapor with air to ensure safety (Simpson's rule being 3 ss. on a handkerchief). The specific gravity of chloroform being four times heavier than that of air, a saturated handkerchief, if held close to the mouth, will displace the air and give a dangerously large percentage of chloroform vapor. 9. In ether, the respirations alone need be watched during its administration. In chloroform, however, the respirations and the pulse need both to be carefully noted.

TREATMENT OF DANGEROUS SYMPTOMS.—1. Nclaton's plan suggests immediate inversion of the patient in case of heart failure. 2. Inhalation of gtt. v. -x. of nitrite of amyl may be given early, the tongue being drawn out to lift the epiglottis. 3. Stimulation, in case respiration is affected, but not entirely suspended, should be employed by means of either ammonia to the nostril, cold douche, or injection of ammonia into the veins. 4. Galvanism, if employed, may be administered by the following methods: (a) Herapath's method (*Lancet*, 1852). The positive pole is placed to the nostril and the negative pole over the diaphragm. A reflex action is thus excited between the fifth pair and the pneumogastric. This is used chiefly in case of respiratory failure. (b) Duchenne's method. The poles are placed directly over both phrenic nerves, on a line with the fourth cervical ver-

tebra. This also serves to stimulate respirations. (c) Packard's method (*Amer. Jour. Med. Science*, 1865). One pole is placed over the upper dorsal spinous process, and the other pole over the apex of the heart. By this method cardiac contraction is induced. 5. Tracheotomy and inflation of the lungs by a catheter passed down the trachea, as suggested by Langenbeck (Berlin, 1859), may be resorted to in desperate cases. 6. Finally, acupuncture of the heart has been suggested, but as yet is not well verified as a safe procedure, nor can it conscientiously be recommended.

CASE OF CARCINOMA OF THE LIVER, WITH REMARKS UPON THE DIAGNOSIS AND TREATMENT OF THE DIS- EASE.

By LOUIS STARR, M.D.,

PHYSICIAN TO THE EPISCOPAL HOSPITAL, ETC., PHILA.

THOMAS —*, æt. forty-nine years, a laborer, was admitted to the medical ward of the Episcopal Hospital on October 26th, 1878. His family history, so far as he knew, was healthy. He had never had syphilis, and had always been moderately temperate in his habits. With the exception of an attack of pneumonia, in early life, he had been little troubled with illness until 1872, when he began to suffer from occasional paroxysms of dyspnea and from dyspepsia and constipation. He had never felt any anxiety about his health, however, until June, 1878. At this date he noticed that the ingestion of food gave rise to pain in the epigastrium, and was followed, after an interval of about five minutes, by vomiting, the material ejected consisting of the recently swallowed food, mixed with mucus and sometimes containing blood. There was also anorexia, constipation, failure in flesh and strength, and commencing jaundice. After the lapse of a month the vomiting became much less frequent and troublesome; the other symptoms, on the contrary, gradually increased in severity up to the middle of September; subsequently there was more vomiting, and his general condition grew rapidly worse. Ten days before coming to the hospital he observed, for the first time, that there was an abdominal tumor. When admitted, he was much emaciated and very weak; his face wore an anxious expression; his skin felt harsh and dry; and there was marked, though not intense, jaundice of both the skin and conjunctivæ, and slight yellowness of the mucous membrane of the mouth as well as of the hair, which was naturally brown in color. His feet and ankles were somewhat œdematous. His tongue was dry, smooth, and lightly coated in the centre; he had considerable thirst, very little desire for food, and when he took anything into his stomach it was almost immediately rejected again. He complained, too, of hicough, of distributed soreness of the abdomen, and of constant sharp pain in the centre of the epigastric region, at times extending through toward the back. His bowels operated two or three times in every twenty-four hours, the motions being partly formed slate-colored, with a tinge of green, and containing a small quantity of blood.

On making an examination of the abdomen, the liver was found to be greatly enlarged, occupying the epigastrium, the right hypochondrium, and the greater part of the umbilical and right lumbar regions.

* Tenn. Med. Society, April, 1858.

† Med. Times and Gazette, 1864: Report of Versailles Med. Society.

* This history was compiled from the ward notes of the resident physician, Dr. J. M. Anders.

These regions, together with the zyphoid cartilage and the right costal border, were thrust outward and to the right, and the umbilicus was displaced about one inch to the right of the median line. The edges of both lobes of the liver could be distinctly traced by the fingers, and were thick, firm, and nodulated, while over the anterior surface several large, and many small, hard nodules could be perceived through the abdominal parietes. The movement of these nodules, as they rose and fell synchronously with the respiratory acts, produced a peculiar wavy appearance at the epigastrium. There was dulness on percussion and tenderness on palpation over the accessible portion of the organ, the tenderness being slight, except over the left lobe, where even light pressure caused considerable pain, and gave rise to eructations of odorless gas and to prolonged hiccough. The upper border of the liver, as determined by percussion, was in the normal position. The pulsations of the abdominal aorta could be distinctly felt, and in contact with the left side of the vessel, just below the margin of the left lobe of the liver, a firm, convex mass, as large as a hen's egg, was discovered. The intestines occupied the left side and the lower part of the abdomen; here there was resonance on percussion and gurgling on palpation; no ascites could be detected. The inguinal lymphatic glands were somewhat enlarged and the abdominal veins moderately distended. There was no cough or difficulty in breathing, and a careful exploration of the thorax revealed nothing but feebleness of the cardiac sounds and a few old pleuritic friction sounds over the lower part of the left chest posteriorly. The urine was voided freely and in proper quantity; was orange brown in color, neutral in reaction; had a specific gravity of 1021; contained a quantity of bile coloring-matter, about the normal amount of indican, and was entirely free from albumen. Nothing abnormal was detected on microscopic examination.

The patient was put to bed and ordered a fluid-ounce of milk, with half a fluid-ounce of lime-water, every hour throughout the day and when awake at night, together with three fluid-ounces of sherry wine and gr. xvj. of sulphate of cinchonidia, in divided doses, during the day.

For the first four days after admission (Oct. 26th-30th) there was a noticeable improvement in his condition. He was more cheerful; was able to sleep better; suffered less from pain, and retained all his allowance of milk and lime-water, except a few doses on the 27th and 28th, which were vomited soon after being taken, the milk being partially curdled and mixed with a small quantity of greenish liquid. Still he had prolonged attacks of hiccough and frequent eructations of gas, and his bowels were too loose, some of the motions being attended with straining, and consisting of little more than blood-stained mucus.

On the 30th a movable, rather firm tumor, three inches in length and two inches in width, was detected above the left iliac region. As there had been no more vomiting, the milk was increased to one and a half fluid-ounces every hour; and, as the cinchonidia appeared to cause slight nausea, it was discontinued, and a powder, consisting of gr. v. of bicarbonate of sodium and gr. x. of saccharated pepsin, given in milk four times daily.

Up to October 31st the morning temperature, taken in the axilla, had ranged about 96.5° F., and the evening, 99°; while the pulse, which was always feeble, varied from 81 to 100 beats per minute in the morning and from 96 to 120 in the evening.

On Nov. 1st the morning temperature was 94.5°; the patient's skin felt cold; his face was haggard; there was great weakness, increased abdominal pain, and a feeble, irregular pulse scarcely perceptible in the left arm, which was considerably swollen, and pitted on pressure. The bowels were more frequently moved, and the passages more clay-colored. There was no vomiting, but obstinate hiccough and great thirst. The milk was increased to forty eight fluid-ounces and the wine to six fluid-ounces per diem, and gr. x. of carbonate of ammonium were administered every three hours. During the night of the 1st he had several large, lumpy stools, and on examining the abdomen next day no trace of the small, movable tumor could be found.

On Nov. 2d, 3d, and 4th his condition was unchanged; the temperature at each observation (8 A.M. and 6 P.M. daily) was 95.5°, and the pulse was very weak, counting from 96 to 108. On the succeeding three days, although there was no alteration in the annoying symptoms—the pain, hiccough, and diarrhoea—there was some gain in strength, a rise in the temperature to the normal line, and a stronger, though more frequent pulse; the swelling of the left arm subsided, and a feeble pulse could be felt in the radial artery at the wrist.

On the night of the 7th he became very much prostrated, and death occurred at 9 A.M. on the 8th, being preceded by a short period of semi-coma. The temperature an hour before death was 95.5° and the pulse 128.

At the *post-mortem* examination, made twenty-six hours after death, the liver was found to be greatly enlarged, and was thickly studded with hard white nodules. These nodules were slightly elevated, round or oval in shape, and varied greatly in size, some measuring scarcely an eighth of an inch, others more than an inch in diameter; a few of the larger were umbilicated. The hepatic tissue was dark-green in color. The gall-bladder, the hepatic duct with its two branches, and the ductus communis choledochus, up to a short distance from its point of entrance into the duodenum, were greatly distended. In the latter position the common duct was partly occluded by pressure from the head of the pancreas. The head of the pancreas was tightly adherent to the duodenum, and rested upon and extended downward to the left of the abdominal aorta; together with the rest of the gland, it was enlarged, nodulated, and much more compact in structure than usual. The celiac glands were greatly enlarged and hardened. There was a *chronic* ulcer upon the lesser curvature of the stomach, and also in the duodenum over the seat of the attachment of the pancreas. The rest of the abdominal viscera were healthy. There was a small quantity of fluid in the peritoneal cavity. There was no marked thoracic lesion, other than extensive pleuritic adhesions on the left side. The tissues throughout the body were somewhat stained with bile. On a microscopic examination, by Dr. Simes, the nodules in the liver, the celiac glands, and the head of the pancreas presented an arrangement of histological elements characteristic of cylindrical epithelioma. The same appearances were also observed in a thin section taken from the margin of the duodenal ulcer. The conclusion, therefore, was that the lesions of the liver, pancreas, and lymphatic glands were secondary to that of the mucous membrane of the duodenum.

Remarks.—The diagnosis of carcinoma of the liver must depend chiefly upon the signs obtained by physical exploration of the abdomen, since the general

symptoms, though they may furnish a clew to the lesion, are far from being characteristic of it.

The general symptoms commonly ascribed to the disease, are, in the beginning, anorexia, flatulence, constipation, distention, and pain at the epigastrium, or right hypochondrium and in the right shoulder, and, later, jaundice and ascites, together with the development of the "cancerous cachexia." Occasionally also there is œdema of the feet and pyrexia.

Of these symptoms, the situation of the pain and the jaundice would direct attention to the liver, but would not indicate the nature of its disease, for the first symptom is common to many hepatic affections; and the second, while it is more frequently present in cancer than in any other organic disease of the viscus, is so often absent that it is of little value as a diagnostic symptom. In fact, jaundice is absent in the majority of instances; thus of 91 cases mentioned by Frerichs, death occurred in 52 without this symptom having been noticed. The icterus, when present, is, in the main, caused by pressure upon the bile-ducts. It consequently varies in intensity according to the degree of obstruction, and, when once developed, never disappears—differing, in this respect, from jaundice, consequent upon catarrh of the ducts or upon obstruction by gall-stones. In this form of icterus, too, the urine, in addition to bile coloring-matter, sometimes contains an excess of uroxyanthin or indican; but this excess cannot be considered as pathognomonic of carcinoma of the liver, as it has been observed in other, very diverse, affections.

Of the other symptoms, complaints of flatulence, distention at the epigastrium, and constipation point to the stomach and intestines. The existence of ascites would simply lead to an examination of the liver, without affording any definite information; and the presence of the "cancerous cachexia" proves nothing except grave interference with the function of nutrition. Again, as hepatic cancer is in the majority of cases a secondary affection, and as it at times gives rise to other lesions—for example, chronic peritonitis or pleuritis—the difficulty of making the diagnosis from rational symptoms is further increased, the attention being diverted to the symptoms of the primary disease on the one hand, or the consecutive disease on the other. The rational symptoms then being, at most, merely suggestive, the main reliance must be placed upon physical exploration of the abdomen.

Such an examination usually shows enlargement of the liver; extending principally in a downward direction, and being frequently of great extent. In the latter case the lower ribs on the right side are pushed upward and outward, and there is a visible tumor in the abdomen having the outline of the liver. There is dulness, increased resistance and tenderness on percussion over the enlarged organ, and on palpation the surface is uneven, and the edges, which can be readily traced, are indurated, thickened, and irregular. This irregularity of the surface and edges, the most pathognomonic of the physical signs, is due to the presence of the cancerous nodules, which vary considerably in size and number, but are always slightly elevated and flattened on the surface, not uncommonly umbilicated, and generally firm and resistant. They are, at times, visible through the abdominal wall, and may give rise to friction-sounds and fremitus, especially on forced breathing. An important negative sign is the rarity of an increase in the area of splenic dulness.

With these physical signs the diagnosis of cancer of the liver is quite easy. In some very exceptional

instances, however, when the cancer is infiltrated, or when a few small cancerous nodules are formed deep in the tissue of the liver, there is only slight enlargement and none of the characteristic irregularities of contour; here no positive diagnosis can be made until after an autopsy. In these cases, too, the difficulty is apt to be augmented by one or more of the rational symptoms being ill-developed or altogether absent.

The disease which is most liable to be confounded with hepatic cancer is syphilitic hepatitis when, in consequence of the formation of cicatrices, the organ has become uneven and lobulated. The clinical history, the presence of other syphilitic lesions, the slight degree of enlargement, and the absence of induration, serve to distinguish the syphilitic from the cancerous affection.

In the case just detailed, the physical signs were so well developed that the diagnosis was easy, even without the confirmation obtained from the patient's age, the absence of syphilitic history, and the existence of the general cachexia and jaundice. At the same time the detection of the small tumor overlaying the aorta and the undue prominence of the gastric and intestinal symptoms indicated that the condition was a complicated one. The nature of the complications was never definitely determined during life; but in the light of the post-mortem examination there is a ready explanation, the tumor being referable to the enlarged pancreas, and the digestive symptoms to the gastric and duodenal ulcers. The rather marked jaundice was supposed to depend upon incomplete obstruction of the bile-duct by a cancerous nodule developed in the fissure of the liver, and this supposition was the natural one, as there was nothing to point to the actual, though far less likely condition, partial occlusion of the common duct by pressure from the head of the pancreas. The fact of the obstruction being incomplete was proved by the presence of bile coloring matter in the evacuation from the bowels.

Among other symptoms, the persistent hiccough and the low temperature are worthy of note. Singultus occurs not infrequently in malignant diseases, especially in those in which there is a tendency to death from asthenia. In such diseases, also, the temperature is frequently low, sometimes falling even below the normal line. Low temperature is almost the rule in carcinoma of the liver, though there is sometimes pyrexia; in these rare cases the elevation of temperature is only moderately high, is commonly of short duration, and is probably due to some inflammatory complication.

In treating cancer of the liver, all that can be done is to meet the troublesome and dangerous symptoms as they arise, and maintain the patient's strength by the use of tonics, stimulants, and proper food. The employment of a light but nutritious diet, into which milk should enter largely as an ingredient, will do much to moderate the digestive derangements and keep up the tone of the system. When there is gastric irritability and an antacid is indicated, lime-water may be added to the milk, and when the bowels are constipated mild laxatives should be administered. Of tonics the best is cinchona, or one of its preparations. If there is much pain, fomentations, cataplasms, and narcotic liniments should be resorted to; and if there is excessive ascites, the trocar is to be preferred to the use of drastic purgatives or hydragogue diuretics.

The great principle of the treatment is to avoid every measure of a debilitating nature, the practical value of an early and accurate diagnosis being to justify the plan of non-meddlesome medication.

Progress of Medical Science.

CONGENITAL ABSENCE OF THE SPLEEN.—Drs. Koch and Wachsmuth, of Altona, report the following case: A large, strongly-built, muscular man, forty-nine years of age, and a tinker by trade, was admitted into the hospital in Altona on December 4th, and died on the 6th. When admitted, he was suffering from high fever and diarrhoea, and presented an indistinct roseolar eruption, but the position of the spleen could not be made out either by palpation or percussion. Physical examination of the chest revealed bronchopneumonia of the right side. At the autopsy the spleen was found to be entirely wanting, and there was no blood-vessel corresponding to the arteria lienalis. All the other viscera were found in their normal positions.—*Berliner klin. Wochen.*, Feb. 10th, 1879.

A CASE IN WHICH THE OPERATION OF LAPAROTOMY WAS PERFORMED THREE TIMES IN THREE YEARS.—Dr. Baumgärtner, of Baden-Baden, reports the following case, which is unique, both because of the number of the operations performed within a brief period of time, and because of the peculiar nature of the indications which led to the last two laparotomies: The patient, a woman, thirty-three years of age, had suffered for four years from a tumor of the left ovary, which had attained a very large size. The tumor was removed on Sept. 28th, 1875. The pedicle was secured in the lower angle of the abdominal wound by a Wells's clamp; and, for the purposes of drainage, Douglas's cul-de-sac was punctured with a trocar, and a drainage-tube carried from the vagina through the opening and out through the abdominal wound. On the fifteenth day the clamp was removed, and the centre of the pedicle at once retracted, leaving a funnel-shaped depression. On the twenty-first day the menses set in, and lasted for five days without any suffering. During this period, and for three days afterward, a bloody discharge escaped from the exuberant granulations on the end of the pedicle. On the thirty-fourth day the wound had entirely healed and the patient left her bed, and a few weeks later returned to work. The menses were subsequently regular and entirely painless, but at each period a small vesicle formed on the spot where the pedicle was involved in the cicatrix. This vesicle ruptured on the second day, discharged blood for four days, and then rapidly healed.

The patient remained well until December, 1876, when, while in the act of lifting a pail of water, she suddenly experienced a violent pain in the pedicle. The pain persisted, and grew gradually worse, and toward the end of February became so severe that the patient was unable to move herself in bed. Micturition was at first normal, but soon became extremely painful. Examination under narcosis revealed no new growth from the pedicle, and no swelling of any sort. The pedicle could be felt as a tense cord. At the urgent request of the patient a second operation was undertaken on March 3d, 1877. The old cicatrix was laid open, and a portion of the omentum, which was adherent to it, was cut through. The pedicle was found to be adherent to the posterior wall and fundus of the bladder, to the omentum, and to some loops of intestine. These adhesions, however, were easily separated. To check the bleeding from the divided omentum it was necessary to use Paquelin's cautery and tie two small arteries. The cauterized

portion of the omentum was brought out through the abdominal wound, and secured there by sutures, and, as a consequence, that portion of the wound did not unite by first intention. The wound finally healed completely, and the patient was again able to go about without pain. Although the pedicle had been completely separated from its parietal connections, and had retracted into the abdomen, a small vesicle formed on the cicatrix at each subsequent menstrual epoch, and discharged blood as long as the period continued.

In January, 1878, the patient again began to complain of severe pain, this time in the region of the right ovary. The pain soon became constant, was markedly increased at each menstrual epoch, and was greatly aggravated by pressure on the abdomen. Up to July the repeated examinations gave negative results; but in that month an examination under an anæsthetic revealed an elongated swelling, about the thickness of a thumb, lying close to the somewhat swollen right ovary. The diagnosis of inflammation of the ovary and tube was then made. As the pain was constantly increasing in severity, and the patient had fever every evening, and was visibly emaciating, a third laparotomy was performed on Aug. 19th, 1878. The incision was made in the middle line, instead of laterally, because a ventral hernia had formed in the lower third of the cicatrix after the second operation. For this purpose the old cicatrix was cut out by a pear-shaped incision, with the base directed downward. After the separation of some slight adhesions, the slightly enlarged ovary, and the tensely distended tube, which was of a deep yellow color, were brought into view, then secured by a double ligature of carbolized silk, and cut off. The uterus, with the stump of the tube, was allowed to fall back into the abdomen, and the wound was closed with silver sutures. The tension in the lips of the wound was removed by a double silver suture introduced at a distance of 4 cms. from the wound, and by an ingenious arrangement of adhesive plaster. The operation was performed under the carbolic spray. On the following morning the patient was entirely free from the pains previously experienced, and suffered only from a sensation of burning in the wound. On the sixteenth day she was able to leave her bed. The ovary was not diseased. The extremity of the Fallopian tube was firmly attached to the ovary, and was converted into a sac as thick as a thumb, filled with thick, cheesy pus. The walls of the sac were in some places exceedingly thin, and in all probability a perforation would very soon have taken place.—*Berliner klin. Wochen.*, February 3d, 1879.

THE BONY MARROW AS A HÆMATOPOËTIC ORGAN.—M. Ponchet, as the result of numerous experiments, investigations, and comparisons, has come to the conclusion that the marrow of the bone is not, as has been claimed, a hæmatopoëtic organ. He states that the generally received opinion that the hæmaglobine belongs solely to the blood-globules is incorrect; it is also found in connection with several other elements. In 1877 he demonstrated the fact that the leucocytes of fish fix hæmaglobine, and since that epoch this has been found to hold true of the leucocytes of the dog, horse, etc. It is also true of some elements of the bony marrow, certain cells of which, when in a state of degeneration, also fix hæmaglobine. M. Ponchet considers it most probable that there is no hæmatopoëtic organ, the red globules being produced either by a sort of spontaneous generation, or by development from leucocytes.—*La Tribune Médicale*, March 30th, 1879.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, July 5, 1879.

ENGLISH MEDICAL STUDENTS.

WE do not know who William Gilbert may be, but we do know that the *Fortnightly Review* is a respectable English journal. Mr. William Gilbert, in the *Fortnightly Review* for January, 1879, after an eulogium upon the character of the medical men of England, makes the following, to us, remarkable statement: "And yet, during the period of their medical education, there is, if police and newspaper reports are to be trusted, no class or profession of young men who come more frequently into collision with the authorities, or exhibit more frequently instances of ungentlemanly behavior. It is computed that no fewer than four hundred out of the two thousand medical students in London, have come directly or indirectly under the notice of the police during the year." We have said that we consider this a remarkable statement. Our English friends are not unwilling to criticise, sometimes unfavorably, American medical men, American medical colleges, and American medical students; but certainly they have never said anything which reflects so severely upon the character of the aspirants for a medical degree as has this writer in the journal from which we have quoted. Whatever may be said of American medical students, it cannot be truthfully stated that they are more frequently the subject of police surveillance than other classes of people. Indeed, we doubt very much if, in the city of New York, during the past year, at a time when we had nearly two thousand medical students, there were twenty-five who ever came under police restriction. It has been thought, in this country, that English medical men were recruited from the ranks of the respectable middle classes—for the moment assuming, with the nomenclature of the English, that the nobility and the gentry constitute the upper classes. But, if the statement we have quoted is reliable, we shall be obliged to think that they are taken from classes who do not

know how to behave so as to prevent interference with their actions by the protectors of the public peace. What can be the cause of this most unbecoming conduct on the part of English medical students? Our writer, strange as it may seem, finds the origin in the malorganization of English medical schools. He says that the fault appears to lie considerably more with their teachers and the bad organization, than in the natural manners and habits of the students themselves. This is an incomprehensible thing to us. We have often had occasion to criticise the management of medical schools in America, and we fear that we shall be obliged to do so upon future occasions; but it has never occurred to us that the bad organization and the bad system of our voluntary schools may make men the subjects of moral reprimand from police justices. We have seen no denial of Mr. Gilbert's statements. Perhaps our editorial brethren in London can explain the paragraphs which we have given our readers. Perhaps they can tell us why four hundred medical students are put under arrest every year in the city of London, and why it is that "more medical students have misconducted themselves in the metropolis during the last session than the students of all other professions put together." This writer complains that the medical schools of London are ill-arranged; that the funds collected for charitable purposes for the hospitals are used for the purpose of establishing medical schools; that every hospital in London thinks it should have an institution for the preparation of men for the profession of medicine; that patients, instead of being treated by gentlemen whose names appear as surgeons and assistant surgeons of the hospitals, are treated by students; and that one patient states that he never saw the same young gentleman two days in succession. Our writer also complains that the dissecting-rooms are in the hospital buildings; and that an odor is plainly discoverable in the wards by the patients. Surely we are not amiss in this country if we hold up our hands in holy horror at this state of things in the greatest city of the world. We have been disposed to think that the crudeness and the poverty in our own institutions were excuses at least for our defective arrangements; but no such charges as these can be truthfully made against the New York, and, we suppose, the Philadelphia and Boston medical colleges and hospitals. Students are not arrested in either of these cities by the hundred, and the odor from dissecting-rooms is not wafted into the wards of the hospitals, and patients are not treated by irresponsible medical students. We rejoice in the thought that in all these respects, assuming, as we have said before, that Mr. Gilbert is correct in his statements, the American medical schools are the superiors of those of London. The faults of our schools are the method of cramming students, which is often fatal to well-digested knowledge; the arrangement of all classes upon the same benches to hear the

same lectures; lack of primary examinations; and want of sufficiently thorough final examinations. But we may safely say that the medical students of America compare, as regards character, with any set of men in the country, and we may also affirm that our hospitals are attended by the gentlemen whose names are attached to their reports.

NEW HAMPSHIRE MEDICAL SOCIETY.

The New Hampshire Medical Society held its annual meeting in the city of Concord, beginning June 17th. The usual number of papers were read and several important topics discussed. The President recommended that a State board of health be established, which is an important step in the direction of preventive medicine. Dr. Twitchell, we fear, unearthed a rough diamond when he laid at the door of rivalry the depreciating opinions so freely given of brother practitioners, and the Society, upon an important ethical question, placed itself in a position closely analogous to that occupied by the Frenchman who refused to save a fellow-being from drowning simply because he had not been introduced to him.

If the advice given with reference to testimony of physicians in court should be faithfully followed, it would at least afford an opportunity for witnesses to avoid bringing additional reproach upon the medical profession through designing lawyers. For genuine ability, the physicians and surgeons in America stand second to none in the world; but one radical defect, however, is that they are too tardy in bringing their claims forward for inspection. Dr. Hall now tells us that he suggested a surgical operation for the removal of biliary calculi more than a quarter of a century ago, and we hope the claim will be sustained for American surgery.

Reports of Societies.

THE NEW HAMPSHIRE MEDICAL SOCIETY.

Eighty-ninth Annual Meeting, held in the City of Concord, June 17th and 18th, 1879.

TUESDAY, JUNE 17TH—FIRST DAY—MORNING SESSION.

The New Hampshire Medical Society convened at Union Hall, in the city of Concord, on Tuesday, June 17th, and was called to order by the President, Dr. A. F. Carr, of Goffstown.

Prayer was offered by the Chaplain, Rev. A. C. Hardy, of Concord, after which the usual committees were appointed by the President.

The Council reported that they had issued twenty-five licenses to practise medicine, and had received twenty-four applications for membership in the Society.

DELEGATES FROM OTHER STATE MEDICAL SOCIETIES.

Dr. C. C. FIELD, of Leominster, Mass., and Dr. M. H. CHANDLER, of Woodstock, Vt., were introduced as delegates.

THE PRESIDENT'S ADDRESS.

The President, Dr. Carr, then delivered the Annual Address, in which he reviewed the history of medical science in New Hampshire. He urged strongly the necessity of establishing a State board of health. Preventive medicine was as applicable to the farm or rural home as to the closely packed dwellings. The address was closed by the history of a case of Colles' fracture, illustrated by drawings.

RABIES.

Dr. C. C. ODLIN, of Exeter, related the history of a case of rabies under his care. The patient was a young man, *æt.* 20 years, who had been bitten by a cat one year ago.

He then delivered an oration on

THE COUNTRY DOCTOR,

in which a graphic account of the responsibilities, the discouragements, and the requirements for success were given. He also argued that alcohol is a food.

MEDICAL ETHICS.

Dr. G. B. TWITCHELL, of Keene, read an elaborate paper upon the above subject. Depreciating opinions of brother practitioners might sometimes be the consequence of thoughtlessness; but in the majority of instances they proceeded from a desire to crush a rival. He blamed, in severe terms, the practice of doctors magnifying themselves through "newspaper puffs;" also the practice of indorsing proprietary medicines with certificates. Such indorsements were the chief encouragement to quackery.

REPORT ON SURGERY.

Dr. J. H. WHEELER, of Dover, gave a summary of his report on surgery, which embraced, for the most part, special references to the contributions to surgery made to the Society previous to the time when it began the annual publication of its transactions.

THE ANNUAL DINNER.

The Society and its guests, including Governor Head and Mayor Brown, of Concord, partook of the annual dinner at the Eagle Hotel, and it was an occasion for several happy post-prandial speeches.

FIRST DAY—AFTERNOON SESSION.

The Society was called to order at 4 P.M. by the President.

The first paper was read by Dr. D. S. ADAMS, of Manchester, on

THE DIFFERENTIAL DIAGNOSIS OF MAMMARY TUMORS.

The paper was elaborate and scholarly.

Dr. WHITTIER, of Portsmouth, then read a paper on

GYNECOLOGY.

The paper was well received by the Society.

MEDICAL HISTORY OF DOVER.

Dr. J. R. HAM, of Dover, read a paper, which contained a brief history of the physicians of the city of Dover since the year 1623.

The paper gave rise to discussion on ethical questions; and the opinion prevailed "that only in cases of the direst extremity, when human life was in peril, and the demands of humanity irresistible, would it be justifiable in a regular physician to attend a case in

the hands of an irregular one, and then he should take the entire control and direction thereof."

OPINIONS AND TESTIMONY OF PHYSICIANS IN COURT.

DR. HILL, of Dover, read a paper on the above subject, in which several instances of legal injustice, begotten by immature medical testimony summarily exacted, were related. The earnest advice was given to refuse attendance in courts of law as witnesses unless opportunity had first been given to consider fully the subjects upon which testimony was required. That portion of the paper was warmly indorsed by the Society.

EVENING SESSION.

The evening session opened with the reading of a report on necrology, by DR. M. C. LATHROP, of Dover. Obituary notices were read of Dr. Ezra Carter, of Concord; Dr. A. M. Winn, of Manchester; Dr. A. Tremblay, of Manchester; Dr. Timo. Kenrick, of Franklin; and Dr. T. H. Jewett, of Berwick, Me. (Hon. member.)

ORIGIN AND TREATMENT OF DIPHTHERIA.

DR. WATSON, of Groveland, read a paper on the above subject, in which he gave his experience in a severe epidemic occurring in May, 1878. Of 110 cases he had 11 deaths. His treatment consisted in strict attention to hygiene, the use of disinfectants, and the internal administration of the muriated tincture of iron in small doses, frequently repeated (four or five drops every half-hour), with a teaspoonful of a saturated solution of chlorate of potassa between. No local applications were made. The nourishment consisted chiefly of cold milk. Alcohol was used only in cases of extreme prostration. Paralysis, blindness, deafness, and anæmia were among the sequela; but total recovery ensued, with only a single exception.

The paper gave rise to a prolonged discussion, and there seemed to be a general concession that the disease was not a constitutional one, and that whatever constitutional conditions might favor it, they proceeded from such influences as malaria and exposure to impure effluvia.

The Society then adjourned to meet Wednesday at 8 A.M.

WEDNESDAY, JUNE 18TH—SECOND DAY—MORNING SESSION.

The Society was called to order at 8 A.M. by the President.

Delegates representing the Society in other medical societies made their reports, which were referred to the Committee on Publication.

SEMI-ANNUAL MEETING.

The semi-annual meeting will be held at Hanover.

TREASURER'S REPORT.

The Treasurer, DR. G. B. HOW, of Manchester, presented his report, which showed a funded capital of the Society of \$1,100.

CHOLECYSTOTOMY.

DR. HALL, of Dover, reported at length from the Maine State Medical Society. He described the Society as very flourishing and well ordered.

Incidentally, Dr. Hall claimed to have first suggested removal of biliary calculi by surgical operation, and that he brought the subject to the notice of Drs. Dixi

Crosby, and E. R. Peaslee over thirty years ago. The more recent claims made with reference to the origin of the operation, both in this country and in Europe, were not well founded.

OFFICERS FOR THE ENSUING YEAR.

The following gentlemen were elected officers for the ensuing year:

President.—Dr. T. J. W. Pray, of Dover.

Vice-President.—Dr. G. P. Conn, of Concord.

Secretary.—Dr. M. W. Russell, of Concord.

Treasurer.—Dr. Lyman B. How, of Manchester.

Executive Committee.—Drs. P. A. Stackpole, of Dover; J. W. Parsons, of Portsmouth; and A. H. Crosby, of Concord.

Anniversary Chairman.—Dr. F. A. Stillings, of Concord.

It was voted to increase the number of members of the Council from ten to twenty, and the Executive Committee was authorized to nominate and to appoint.

The President and Vice-President were introduced, and Dr. Pray returned thanks for the honor conferred upon him, and pledged his best efforts for the advancement of the interests of the Society.

After the adoption of resolutions on certain ethical relations, and a minute inquiry with reference to a case of hydrophobia occurring in Concord, the Society adjourned.

THE AMERICAN NEUROLOGICAL ASSOCIATION.

Fifth Annual Meeting, Held in the City of New York, June 18, 19, and 20, 1879.

WEDNESDAY, JUNE 18TH.—FIRST DAY—AFTERNOON SESSION.

The Association was called to order at 3 P.M., by the Secretary, DR. E. C. SEGUIN, of New York, who introduced the President, DR. F. T. MILES, of Baltimore, Md.

The President thanked the Association for the honor it had conferred upon him in his absence, and proceeded with the regular order of business.

On recommendation of the Council, the resignations of the following gentlemen were accepted: Dr. A. McLane Hamilton, Dr. D. B. St. John Roosa, and Dr. E. G. Loring, of New York; and Dr. Swan M. Burnett, of Washington, D. C.

The Treasurer's report was read, and showed a deficit of \$20.89, which the Treasurer stated would be covered when the annual dues were paid.

CANDIDATES FOR MEMBERSHIP.

DR. WILLIAM A. HAMMOND nominated Dr. W. J. Morton, of New York; and DR. E. C. SEGUIN nominated Dr. R. W. Amidon, of New York, for membership in the Association.

The essays of the candidates were referred to the Council for examination and report.

MISCELLANEOUS BUSINESS.

Under the head of miscellaneous business an amendment to the constitution was made providing for the transaction of all business by the Council subject to revision and approval by the Association.

An amendment was also offered by DR. GREY, of Brooklyn, providing for forfeiture of membership by non-attendance upon two consecutive meetings, unless satisfactory excuse could be rendered to the Council.

GUNSHOT-WOUND OF THE NECK—PARALYSIS OF THE CERVICAL SYMPATHETIC, FOLLOWED BY INSANITY,

was the title of a paper sent by Dr. H. M. BANNISTER, of Chicago, Ill., and read by the Secretary.

The peculiarity of the case reported was, that it exhibited an apparent consequence of these injuries which had not been heretofore reported. The ball from a revolver entered upon the left side of the neck between two and three inches above the clavicular origin of the sterno-cleido-mastoid muscle, directly upon its anterior or inner margin, and, passing backward and a little downward, was lost in the tissues.

The leading symptoms were exophthalmos of the right eye; enophthalmos of the left eye; inequality of the pupils, the right being the largest; and a difference of 1° C. in the temperature of the two sides of the face. There was no tenderness upon pressure on any part of the neck, no ptosis, and no history of any lesion of important nerves save the sympathetic. It was as nearly a case of uncomplicated injury to the cervical sympathetic as he had seen recorded. The chief feature of interest was the connection the case had with mental disorder. There was no history of special neurotic tendency or symptoms of mental disorder antedating the reception of the wound, and no known cause of the insanity, except the wound. He had delusions, hallucinations, and occasionally signs of paralysis. The patient believed himself to be the bishop of Chicago, and thought he had power to make people tell their secrets.

Dr. WILLIAM A. HAMMOND, of New York, remarked that Dr. Bannister had barely glanced at the most important part of his case. He had alluded to the fact that the man had *délire en grandeur*, but had avoided altogether association of disease of the sympathetic nerve with the general paralysis of the insane.

He was astonished that so good a scholar as Dr. Bannister should pass so lightly over such an important point. Lesion of the sympathetic existed in most, if not all cases of general paralysis of the insane. In this case whatever brain lesion there was must have been secondary to the injury of the sympathetic, and, therefore, possibly originated in the latter.

The case also went to confirm the opinion that the mind, whatever it was, existed in gray nervous matter wherever found, as well as in the brain itself.

Dr. E. C. SEGUIN, of New York, remarked that before accepting the case as one of general paralysis of the insane, it would be desirable to scan the semiology. The only symptom alluded to in the report that would lead to that supposition was the *délire en grandeur*. Dr. Bannister had not mentioned fibrillary movements of the muscles, peculiar speech, epileptiform attacks, or other varieties of ambitious notions, and simply stated that at one time the patient supposed he was bishop of Chicago, and that he also had power to make people reveal their secrets. But, leaving aside the psychological symptoms, Dr. Bannister had not mentioned the physical symptoms, which were never absent in general paralysis of the insane. He should admit that there was chronic cerebral hyperæmia simply, but should be reluctant to classify the case with general paralysis of the insane.

Dr. HAMMOND remarked, he was the first to call attention to the fact that, in general paralysis of the insane, physical symptoms manifested themselves before mental symptoms were developed. He had been told by a number of superintendents of insane asylums that they had never, rarely if ever, hardly ever, at least, seen a case of general paralysis of the insane in its earliest stages. Consequently, those who had

written upon the subject really knew nothing about the primary symptoms, which were physical.

Dr. PUTNAM, of Boston, objected to the admission of the evidence regarding the patient's psychological condition, and could not see why this injury, situated in an important nerve tract, should act in any other way than through peripheral disorders.

Dr. J. J. PUTNAM, of Boston, exhibited a new

RHEOSTAT,

made of German-silver wire, wound upon pegs, and having a sliding clasp, by means of which the intensity of the current could be steadily and conveniently increased, without liability of breaking the current. It was to be attached to the battery as an accessory circuit.

Dr. Putnam also made some remarks with reference to

BATTERIES OF HIGH AND LOW TENSION.

Dr. HAMMOND, of New York, remarked that rheostats were really of no value whatever in the practice of medicine. The only practical apparatus was something which enabled us to bring a greater or smaller number of cells into the circuit at the same time, and then some temporary arrangement for making and breaking the circuit.

Dr. PUTNAM allowed all that Dr. Hammond said was true; but the apparatus presented simply permitted of gradual increase in the intensity of the current, and small batteries lasted longer when all the cells were used than when only a part were employed.

Dr. BEARD, of New York, remarked that at one time he experimented with all forms of rheostats, but after a while he got out of the way of using any. He thought that his experience was not at all exceptional. Theoretically, they sounded well, and appeared well when written out in full detail; but his experience had been that they possessed no special practical value. For him, pressure of the sponge made a very good rheostat.

Dr. A. D. ROCKWELL, of New York, thought the rheostat suggested by Dr. Beard—namely, pressure upon the sponge—a rather slipshod method of management. Every movement of the sponge upon the body might cause a variation in the strength of the current, and for that reason it was difficult to give it exact control. He agreed that there was a vast amount of unnecessary refinement in apparatus employed for the application of electricity; but he had come to believe, at the same time, that some refinement was essential, therefore he employed the rheostat much more than formerly.

Dr. MILES, of Baltimore, remarked that he used the water rheostat constantly, and found it a very great convenience, especially when using electricity on children.

Dr. E. C. SEGUIN remarked that it was next to impossible to prevent interruption of the galvanic current by the wire apparatus sliding bar, and thereby avoid giving disagreeable shocks to the patient. He thought the chief advantage of a rheostat was the ability it gave to commence with a large number of cells, and gradually increase the current until sufficient sensation was produced—the sensation of the patient being the guide. An objection to the water rheostat was that while it answered very well up to a certain point, where the metallic points were within a short distance of each other, it was almost impossible to bring them nearer without bringing them together, and thus give rise to a shock. The attachment of a micrometer screw and guard would be advantageous.

Dr. J. J. MASON remarked that, for a mild current,

a metallic rheostat was preferable to a water rheostat, because of the great resistance offered to the primary current by the water, consequently a diminution in the intensity of the current. Anything like an improved rheostat he regarded as important.

The Association then adjourned, to meet at 8.30 P.M.

FIRST DAY.—EVENING SESSION.

The Society being called to order by the President, a paper was read by DR. GEORGE M. BEARD, of New York, on

MORBID FEAR AS A SYMPTOM OF NERVOUS DISEASE.

The emotion of fear might be a normal one, varying in degree and kind with race, sex, and individual. It might also be a truly pathological symptom, evidencing in such case disorder of the nervous system. Normal and morbid fears might shade into each other, so that it was difficult to draw the line between them.

These morbid fears might be classified and named for convenience of study, and for the purpose of preventing their confusion with hysteria, hypochondria, dyspepsia, and actual insanity, to which conditions they were often referred. There were quite a number of morbid fears associated with neurasthenia without delusions or hallucinations.

The following classification might be given :

Astraphobia (first described by Dr. Beard a number of years ago), in which there was great fear of lightning during and before thunder-storms, that fear being preceded and accompanied by headache, numbness, pain in the back, nausea, vomiting, and even convulsions. In one of his patients suffering from that symptom, the condition was inherited from the grandmother.

Agoraphobia was a name given by Westphal, of Germany, to those having a fear of places. The term was not an accurate one, and *topophobia* should be used in its stead, agoraphobia being only a species of topophobia, and embracing those cases in which there was a fear of open squares. As an illustration of topophobia, one of his patients could walk up Broadway without fear or difficulty, on account of the numerous stores and side-streets, into which he knew he could run, in case of supposed danger presenting itself; but he could not walk up Fifth Avenue; he could not visit the country at all. He was a tall, vigorous man, and had no other symptoms of cerebral disturbance. The cases often took an opposite phase: the patients were unable to go to certain places; perhaps where they were first attacked with the evil symptoms. Some found it difficult to go on long journeys. A patient in a distant city wrote that he was coming to visit him, but after getting part of the way he had to return. Some persons had a fear of confined places. A gentleman suffering thus was obliged to camp out in the summer and sleep in a very large room in winter. He finally had to leave the city and become a farmer.

Anthropophobia, that Dr. Beard had lately described, had for its symptoms an aversion to society; fear of seeing any one; sometimes there was fear of women alone; sometimes, as in one of his patients, fear of respectable women alone.

Pathophobia, or fear of disease, was generally known under the name of hypochondriasis. Photophobia was a term that might be applied to some patients who feared that they might fail if they made an attempt to do anything.

Myophobia, or fear of contamination, had lately been described by Dr. Hammond.

In regard to all these different forms of fear, the following general propositions were made:

1st. They were symptomatic of functional, rarely or never of organic disease. They were not, according to his experience, found in insanity or sclerotic conditions, and were no form of that disease. The morbid fears of the insane were delusions or hallucinations.

2d. The symptoms might come and go suddenly.

3d. They often were the result of disorders of the reproductive organs in male and female, but might continue long after such disorder had been cured.

4th. They rarely existed alone, but almost always were associated with other symptoms of disorder of the spinal cord or brain, especially of the brain. Among those symptoms were palmar hyperidrosis, dizziness, numbness, shooting pains in the extremities, oxaluria, etc. All those symptoms were by no means uniformly present. The patients might be of great muscular development, and capable of great bodily toil. The treatment required both constitutional and local measures. The former included the whole array of sedatives and tonics; electricity, bromides, counter-irritation at the back of the neck, and counter-irritation of the bowels by means of cathartics. The local troubles should be appropriately treated. The cases could be permanently cured, but not in any short time.

DR. J. J. PUTNAM, of Boston, asked if the vertigo ever occurred without being excited or accompanied by any motor idea or intention?

DR. BEARD thought that it did.

DR. J. J. MASON, of New York, referred to the very common occurrence of fear of lightning and storms, especially with women, and asked why this should be distinguished as a special morbid symptom?

DR. BEARD said that in the cases given there was much more than ordinary fear. The patients often suffered from nausea, vomiting, dizziness, and even convulsions.

DR. A. D. ROCKWELL, of New York, said that, without being able to give any special examples to the contrary, he nevertheless could not accept the statement that these fears were always the result of functional, rather than organic derangement.

DR. BEARD, in reply, said that it was his experience that the facts were as he stated.

DR. E. C. SEGUIN, of New York, remarked that while the minute study of a symptom of this class was very interesting, it was hardly profitable in practice. He had always found numerous other symptoms with those described by Dr. Beard, and those others were generally of the greater importance. It was better also to look at the symptoms as a whole; to study the patient as a physiological unit, rather than investigate some particular symptom, which might be more curious than important. His experience agreed with Dr. Beard's in regard to the existence of functional derangement only in connection with these morbid fears.

DR. BEARD, in reply, said that he thought the great aim should be to discover the true pathological state of the patient. A study of the symptoms about which he had written helped very often in this direction, and was therefore valuable for diagnosis, prognosis, and treatment. These morbid fears were symptomatic of cerebraesthesia (brain exhaustion), and in a large proportion of the cases (but not in all) that cerebraesthesia originated in the genital organs—uterine displacements and disorders of the neck of the uterus—and disease of the prostatic urethra in the male, from natural or unnatural excess.

DR. WEBSTER, of New York, by permission of the Society, related a case of morbid fear that had come

under his notice. A woman, 40 years old, had always from infancy been afraid of severe storms, high winds, thunder and lightning, and to those who were acquainted with her it seemed as though she was insane at such times. When a storm arose at night, for instance, she would rouse the whole house and walk the floor in the greatest distress until it subsided. She did not suffer any pain, but only from nausea. He was told that her mother, while pregnant with her, had been severely frightened by a thunder-storm. The patient's condition was attributed by the friends to that fact.

Dr. ——— agreed with Drs. Beard and Seguin that morbid fears were evidences of only functional disturbance. In his experience they were very often associated with lithuria or oxaluria.

Dr. SPITZKA thought that there could not be any sharp line drawn between morbid fear in the sane and insane. It was a frequent accompaniment of insanity, and often the first symptom of it.

Dr. Spitzka then related the following case of

REMARKABLE SYMPATHETIC DISTURBANCE:

A young man, a persistent masturbator, while engaged in the act suddenly heard a noise like the crack of a pistol in his head. From that time he became melancholic; he noticed that one-half of his face, on the side where he had heard the sound, was hotter, and perspired more than the other. In about three weeks a carbuncle appeared on the back of the neck near the third cervical vertebra. After this, irregular yellow spots appeared on the affected side of the face, the parts atrophied, the hair became white and there were differences in the pupil. His mind became somewhat affected. It was suggested that the sound was probably due to a sudden vascular disturbance.

In a short discussion which followed, Dr. Spitzka referred to the fact that experiments and investigations showed the sympathetic system to be independent of mental disturbances, and that it could be greatly injured or diseased, and yet the mind not be at all affected.

The Society then adjourned to meet Thursday, at 2.30 P.M.

(To be continued.)

THE PHILADELPHIA COLLEGE OF PHYSICIANS.

Regular April Meeting.

(Reported for THE MEDICAL RECORD.)

UNUNITED FRACTURE OF THE TIBIA OF TWELVE YEARS' STANDING—PRESERVATION OF A USEFUL LIMB.

Dr. WILLIAM S. FORBES brought a man before the college and read the following history: A seaman, thirty-six years of age, and in full health, was admitted to the Episcopal Hospital three weeks ago with an ulcer on his leg. His ulcer is now well; but he has an ununited fracture in middle of right tibia. No bone is thrown out. The two fragments are held together by a short, dense, fibrous deposit. There is a limited amount of motion between the fragments. The patient can walk about without pain, and without the support of a splint, bandage, or cane. Has often walked as much as fifteen miles a day, and carried heavy weights long distances. Examination shows that the fibula was not broken, and hence serves as a splint to the ununited fragments of the tibia. This fact explains the sensation of pulling experienced at the upper tibio-fibular articulation after long walks.

The fracture of the tibia took place twelve years

ago, the soft parts being cut to the bone, and the latter shattered by a blow received from the end of a broken rope. He was in the Pennsylvania Hospital for fourteen months after the accident. During this period, and for twenty-two months afterward, a tin splint was worn around the leg, and the patient moved about in a rolling chair. At the end of three years he got out of his chair, and, after using a crutch for a short time, abandoned it for a cane. Since then he has led an active life, and has never been laid up or disabled in any way.

In all this time no change has occurred in the limb. Just at the line of fracture, and a little above and below it, the bone is covered by dense fibrous tissue, serving as a stay-ligament to hold the fragments in apposition. This ligament becomes very tense when the man stands on that leg.

The affected extremity is just half an inch shorter than the sound one. This slight shortness is no doubt the result of absorption of the extremities of the fragments. The fibula on the fractured side is not bent or curved, nor is it enlarged to any perceptible degree. In this respect it differs from the one in the museum of St. Thomas' Hospital, mentioned by Dr. Norris in his "Contributions to Practical Surgery," in which the increase in size was great.

It was hard to account for ununited fracture in the case under consideration, as the man had no taint or vice of system, and as he had received proper treatment at the hands of excellent surgeons. There seemed to have existed in this man what Sir James Paget calls "a simple defect of formative power;" a defect which cannot be explained, and which seems the more remarkable when we observe the many changes which may at a later time be effected, as if to diminish the evil of the want of union.

ILLUSTRATIONS OF THE VALUE OF TEALE'S METHOD OF FORCED DILATATION OF THE SPHINCTER VESICÆ IN INCONTINENCE AND EXCESSIVE IRRITABILITY OF THE FEMALE BLADDER.

Dr. ADDINELL HEWSON read a paper with the above title, giving the history of six cases of incontinence and irritability of the female bladder treated by forced dilatation.

CASE I.—Female, æt. 30. Dr. Hewson had treated the patient for severe vaginitis and endometritis, a result of gonorrhœa. Examination revealed both sets of labia much swollen, and great tenderness of the external genitals. Prolapse and retroflexion were also both detected. There was great irritability of the bladder. These troubles were all relieved by the use of a douche-bottle, double catheter, and medicated sponge-tents. Her retroflexion was subsequently treated by means of a whalebone intra-uterine stem-pessary. Six months later Dr. Hewson was suddenly called in haste, and found patient suffering intense agony from inability to urinate. An explanation was found in the fact that the menses had been suddenly arrested on the second day following exposure to severe cold, and that since that time the patient had suffered from lumbar pains, headache, constipation, and nausea. Great crethism had arisen, which had been relieved by severe scratching. Great tenderness of the abdominal walls was found to exist. The catheter was introduced, but only removed f 3 ss. of high-colored urine free from pus and blood. The introduction of the catheter caused the patient to scream with pain. Inspection showed the case to be one of acute sphincterismus with great inflammation of the parts.

Anesthesia was produced by rapid breathing, and

an Ellinger uterine dilator was passed the whole length of its blades into the bladder without causing any pain or bleeding. The operation, which lasted fifteen minutes, was free from pain, although the patient was fully cognizant of what was going on.

The dilatation was followed by most complete relief. No dressing to the parts was ordered, but she was told to remain in bed. Since that time there has been no return of the bladder trouble.

CASE II.—A widow lady, who had been under treatment for prolapse, attended by great irritability and catarrh of the bladder. When summoned to see the patient on February 22, 1876, Dr. Hewson made a digital examination, and found the bladder excessively sensitive to the touch. The patient's sufferings were so great upon this occasion as to make her act and look like a maniac. Questioning elicited the fact that the great irritability of the bladder had existed ever since the birth of her first child, sixteen years ago.

Teale's method of dilatation was at once resorted to without any attempt at producing anaesthesia. The Ellinger was passed quickly, without any warning, into the bladder. In twenty minutes the urethra was sufficiently dilated to allow of the passage of the index finger into the bladder. There was no bleeding, and all inclination to pass water constantly was removed. The tenderness along the line of the operation was alleviated by the application of some wet clay. The patient has never had any sign of sphincterism since that time.

CASE III.—Robust married lady, *æt.* 38; barren. This barrenness, said to be due to prolapse and retroflexion, was treated by the introduction of a Meigs ring-pessary. This instrument was allowed to remain three years *in situ*. Two years after the removal of the pessary the lady became Dr. Hewson's patient, complaining of vaginitis and irritability, which, she said, had existed ever since the ring-pessary had been first introduced. This vaginitis was treated by Dr. Hewson by injections and applications. The speculum showed indurations and thickening all around the place where the pessary had been. On February 22d the patient had an intense attack of irritability and incontinence. The patient preferring not to be rendered insensible, the Ellinger dilator was at once introduced, but very cautiously, on account of the spasm of the sphincter. The dilatation was steady and forced, rather than rapid. The operation occupied half an hour. The patient seemed to be relieved.

Orders were left that clay should be applied constantly to the parts. Recovery was slow, but sure. The irritability recurred several times, but each attack was lighter. The patient is now entirely free from her old trouble.

These three cases occurred all in one day.

CASE IV.—A widow lady, who consulted the writer for a large fibro-cystic tumor, which had been diagnosed by the late Dr. W. L. Atlee as springing from the broad ligament and body of the uterus. Even at that date the patient complained of troubles with her bladder.

Some six weeks later, when the tumor had diminished several inches under the earth-treatment, the symptoms of vesical irritability became more marked. A vaginal examination revealed most positive sphincterism, without any thickening or induration. Analgesia was produced by rapid breathing, and the whole length of the urethra was then rapidly dilated by means of the Ellinger instrument. Clay was applied daily for a short time. There has never been any return of the bladder symptoms since the opera-

tion. The tumor has decreased in size at the rate of two inches per month.

CASE V.—Married lady, *æt.* 43, still menstruating, consulted Dr. Hewson in 1877 about bladder troubles. Examination showed a large, tender, fatty growth in the right side of the abdominal walls. There was not much sphincterismus. The patient said that this growth was the result of a blow received on the parts some years ago, and said that the tumor and bladder symptoms developed constantaneously. The clay-treatment dissipated the tumor entirely in the course of four weeks, but the bladder symptoms persisted. There was great difficulty experienced in detecting the orifice of the urethra, but when found the Ellinger was rapidly introduced. The introduction was the cause of much pain to the patient. The dilatation lasted fifteen minutes. There has not been any return of the trouble since. Subsequent inquiry traced the inception of the bladder trouble to the birth of her first child, twenty-three years previously.

CASE VI.—Patient aged 45. Had suffered constantly since the birth of her first child, twenty-three years ago, with incontinence. When first seen by Dr. Hewson she had an expression of the most extreme anxiety and despair. Analgesia was brought about in ten minutes by rapid breathing. Examination then revealed sphincterismus without thickening of the tissues, but with well-marked retraction.

The Ellinger was introduced and its blades passed completely into the bladder. Dilatation lasted five minutes. Clay dressing was then applied. The results in this case were of the most flattering description. Complete relief followed rapidly upon the operation.

In closing, Dr. Hewson desired, as the title of his paper showed, to give the fullest credit to Mr. Teale for the origination of the idea of the method of treatment employed, but to make known his own ignorance of Mr. T.'s *plan* of procedure. He had operated in all his cases with the patient reclining on the left side, the orifice of the urethra being much more accessible in that position than in any other. The entrance once effected in this manner by an instrument, the latter can be readily and quickly glided along the passage by simply moving its handle or near extremity forward in the segment of a circle, provided that the curve of the instrument is looking backward.

After the reading of the foregoing paper, DR. GOODELL spoke as follows:

"I have performed the operation of forcible and rapid dilatation of the urethra some fifty times at least, and have so often cured by it bladder troubles of long standing, that I wish to add my testimony to that of Dr. Hewson as to its efficiency. The female urethra does not possess a true sphincter, but, from the meatus urinarius exclusive to the neck of the bladder inclusive, it is surrounded by a network of muscular fibres, which firmly constrict it, and act the part of a powerful sphincter. It is the spasmodic or the organic contraction of this broad belt of fibres that makes woman more liable than man to urinary disturbances.

"While warmly advocating the operation of rapid dilatation of the urethra, I wish to point out certain risks attending it, to which Dr. Hewson has not adverted. One is incontinence of urine. This result I have not thus far seen in any of my own cases, because I dilate simply to the extent of the girth of my index finger, which is of medium size, and no further. But I have twice met with it in cases operated upon by other physicians, and in each the thumb had been forced in. This experience has led me to think that

there is danger in making the dilatation too great. The other risk is that of hemorrhage, either external, from the rent often made in the upper margin of the meatus, or internal—into the bladder—from the rupture of the tense and thin fold of mucous membrane often found at the neck of the bladder. I have several times met with the former, and have been obliged to use styptics. On one occasion I was compelled, in a pregnant woman, to close the rent by a metallic suture, passed deeply in, before I could check the bleeding. I have occasionally met with cases of internal bleeding, but, although one of them lasted for three days, I have not found it needful to interfere by styptic injections.

"I would further remark that in the selection of cases for dilatation it is important to distinguish between purely hysterical cases and cases in which there exists a real tonic contraction of the urethral muscular fibres. For while the operation almost always benefits the latter, it will sometimes increase the urinary troubles in the former."

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, April 28, 1879.

DR. FREEMAN J. BUMSTEAD, PRESIDENT, IN THE CHAIR.

EXTIRPATION OF THE BONES OF THE NOSE AND MOUTH BY THE USE OF THE SURGICAL ENGINE.

DR. D. H. GOODWILLIE read a valuable paper upon the above subject, which will be published in a subsequent number.

INTRA-VASCULAR ALIMENTATION: THE NUTRITIVE VALUE OF PEPTONES.

DR. GEO. B. FOWLER read an exceedingly important paper upon the above subject, in which he brought forward peptones as an article to be introduced directly into the circulation in cases in which nutrition could not be properly sustained by gastric or rectal alimentation.

Dr. Fowler then traced the processes of digestion, and demonstrated how nutrition was maintained by albuminates, hydro-carbonaceous substances, salines, and water. The practical results of introducing blood directly into the circulation had amounted to but very little indeed. We could not throw blood into the veins and expect its *assimilation*, because it was a tissue, and not a reservoir of food prepared for assimilation. The cases of success in transfusion of blood in the lower animals were those in which there had been severe loss of blood, and the vessels required the stimulus of distention. There was a class of cases, such as exhaustion from traumatic hemorrhage, in which the stimulus of distention was required, and the transfusion of blood in such cases had in many instances been successful.

When, however, blood was taken into the stomach it was not absorbed as blood, but underwent a change the same as other food. Such change was necessary, and could not occur when the tissue blood was thrown immediately into the circulation. With the view of introducing nutritive material directly into the circulation, Drs. T. G. Thomas, J. W. Howe, W. E. Bullard, and others, had resorted to intravenous injections of *milk*. The position had been taken that milk was not unlike chyle, but Dr. Thomas's recommendation of it had been based upon practical results rather than upon chemical or physiological bear-

ings. Dr. Fowler then proceeded to criticise the tables that had been made with reference to milk and chyle, and claimed that intravenous injections of milk were unphysiological. There was no constituent in chyle similar to the casein of milk. The milk globules were enclosed in an albuminous envelope, and were soluble only at a temperature of 115° F.; and he was not able to understand how any of the proximate principles of milk could be digested when introduced directly into the circulation.

ALBUMINOSE OR PEPTONE FOR INTRAVENOUS ALIMENTATION.

Dr. Fowler then brought forward a new article, albuminose or peptone, to be used for intravenous injections to sustain nutrition. It was digested albumen. It was the result of the action of gastric juice upon albuminous substances. It differed from albumen in its chemical reaction and physical properties. Dr. Fowler then gave a demonstration of the difference between the new preparation and albumen, as shown by various reagents, such as mineral acids, heat, alcohol, ferrocyanide of potassium, etc., etc.

The substance was obtained from finely chopped beef, by continuous boiling for forty-eight hours or more, under pressure with a weak solution of hydrochloric acid. The reactions of the albuminose, as distinguished from albumen, were very marked, and the new product was not precipitated by heat. Dr. Fowler proposed to use this substance as a substitute for milk and blood for intravenous injections to sustain nutrition. He had experimented upon several animals, and had injected large quantities in cats and rabbits, and in each instance it had been assimilated; that is, it did not reappear in the urine.

Of its nutritive value there was considerable evidence. As an example, a rabbit had been sustained for five or six days by rectal alimentation [the new product being used]; there were no feces, and the animal did not lose flesh. Dr. Fowler then made special reference to a case which he saw in consultation with Dr. Mundé, and in which resort was had to intravenous injection of the new substance, and with permanently beneficial results. About $\bar{\text{v}}\text{ij}$. of the liquid, corresponding to $\bar{\text{v}}\text{vi}$. of meat, were thrown into the veins, and the vomiting and all other disagreeable symptoms dependent upon perilous hemorrhage from cancer of the uterus rapidly subsided, and the patient was soon able to take food by the stomach with comfort.

The paper being before the Society for discussion, Dr. P. F. MUNDÉ gave a somewhat detailed history of the case to which Dr. Fowler had referred. The hemorrhage was exceedingly profuse, and the exhaustion was so great that he did not remove her from the table for twelve hours; at the end of that time she was removed, her pulse was rapid and feeble, and she was unable to retain anything upon her stomach. On the following day she was in very much the same condition, and was able to retain only small pieces of ice dipped in brandy. The median cephalic vein was exposed, and two and a half or three ounces of the albuminose was injected by Dr. Fowler, and about an ounce escaped into the cellular tissue, on account of an accident relating to the instrument. The fluid that found its way into the cellular tissue was *readily absorbed*.

The patient's pulse and temperature rose, fell a few hours afterward, and she had marked rigor, which was soon followed by well-marked, though not severe, symptoms of collapse. The symptoms, said Dr. M., were almost identical with those developed in one of Dr. Thomas's cases, in which recovery took

place after intravenous injection of milk. The patient became delirious; so much so that it became necessary to administer opium to keep her quiet. On the following morning she was very comfortable and was able to take milk, brandy, and water; her pulse was 102, and her temperature was about normal. From that time she did very well, and Dr. Mundé thought that she would not have lived two days had she not received the nourishment afforded by the intravenous injection.

Dr. J. C. DALTON remarked that ever since the time when transfusion of blood first attracted the attention of the profession, it had passed through a regular series of periods in which it had been adopted and used with a great deal of enthusiasm and expectation, and then dropped and allowed to remain in oblivion perhaps fifty or seventy-five years, and again taken up with certain modifications and claimed improvements. Now we had the transfusion of other substances besides blood, and in addition to milk, which had been used in several cases, Dr. Fowler had called the attention of the profession to the value of peptone for intravenous injections to sustain nutrition. Peptones were bodies which we did not, by any means, fully understand, and probably the same could be said of all albuminous substances.

There were certain characteristics well understood, such as that they were nitrogenous, nutritious, non-coagulable by heat, etc., etc.; but it was not quite so easy to understand why it was that they did not go out of the blood-vessels. He regarded it as a suggestive idea to prepare peptones artificially, and to use them for intravenous alimentation. He thought that Dr. Fowler had employed an extremely appropriate term—namely, "*intravenous alimentation*." The term suggested to him the difference between the object aimed at by the injection of peptones and that sought by transfusion of blood. When blood was transfused from one person to another it was not for the purpose of alimentation; at least, where it had been so used, it had not been successful. But in cases in which there had been great loss of blood, in which there was no want of ability to take food, and in which there was a simple deficiency in the quantity of blood, it was his conviction that under those circumstances nothing had been found comparable with blood for intravenous injections. A certain quantity of blood was necessary to sustain life and keep the machinery in motion, and when from loss of blood the machinery was about to cease to move, the introduction of a small quantity of blood into the veins—it did not require a large quantity—stimulated it to renewed action in a manner we did not understand. In the cases, however, in which there was a demand for nutrition another condition of things existed.

An objection to injection of blood, perhaps that most frequently urged, was the difficulty of the operation. Dr. Dalton respectfully suggested that that was not an objection worthy of consideration. For nearly all operations that were valuable were difficult, and if an operation was legitimate and useful its difficulty was not a fatal objection to it. It was equally difficult to find a vein in exhaustion, either from hemorrhage or collapse, and when once lost it was very difficult to find it again. There was another point, and that was with reference to the meaning of the threatening symptoms which manifested themselves after transfusion of blood or intravenous injections, such as delirium, pain in the head, oppression of respiration, etc. He had a strong conviction that the exact mode in which the mechanical operation was performed had much to do with the development

of those symptoms. It was not the simple injection of air bubbles into the veins that constituted the most dangerous part of such an operation, for that might occur without producing fatal results, but in some manner the heart's action was arrested for other causes, such, perhaps, as the fact that the fluid was a little too warm or a little too cool, or it was thrown in a little too rapidly, or was a little too strong, or a little too weak. He believed that the disagreeable symptoms were in some way connected with the mechanism of the operation.

In conclusion, Dr. Dalton thought it important to bear in mind that the condition of a patient suffering from exhaustion due to severe hemorrhage was different from that induced by lack of nutrition.

The Society then adjourned.

Correspondence.

A RECENT MEDICO-LEGAL CASE OF INTEREST.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—The late trial in Philadelphia of Edward Parr for the killing of his daughter, Susan Irwin, and the subsequent suicide of the condemned murderer, are not devoid of several points of very general interest to the medical profession throughout the land. In their efforts to discover some feasible defence of the act of murder committed by Parr, the defending counsel came upon the marks of an old fracture of the prisoner's skull, which led them to adopt the novel theory that the murder had been committed by Parr under the influence of a fractured skull and injured brain which had never recovered its wonted condition of health, but which had been subject to chronic irritation and inflammation. An oculist of experience and reputation, who was engaged by the counsel for the defence, testified that he had made an examination of the prisoner's eyes, and had found them in an abnormal condition, which condition must have been caused either by a fracture or by a tumor of the brain. Among the physicians placed upon the stand were the coroner's physician, Dr. Henry C. Chapman, and Drs. John H. Packard, William Hunt, and John Ashburst, Jr. The testimony of these gentlemen varied somewhat; most of them agreeing, however, upon the fact that the skull did present the marks of an indentation or depression just above the attachments of the ear, which was presumably the result of an old fracture. One physician testified that the prisoner seemed to have some abnormal sensations in the vicinity of this scar when it was pressed upon; and, upon cross-examination, stated that a low state of inflammation might exist for years in a man's brain. The other gentlemen did not commit themselves so positively with regard to the probable origin of the depression or irregularities in an old fracture, and all of the testimony was non-committal as to whether there was or was not a depression of the internal table of the skull.

In spite of the ingenious argument of the defence, the jury brought in a verdict of murder in the first degree. The prisoner was placed in the dock, and the judge had just passed sentence, when Parr half raised himself from his seat, and then fell heavily forward on the floor. Physicians were at once summoned, and proceeded immediately to treat the patient for strychnia poisoning. They gave him a *hypodermic injection of morphia and injections of turpentine and whiskey*, and

a stomach-pump was also used. After working for some time, the doctors said that it would be a miracle if the man's life were saved. The ingesta removed from the stomach by the pump were preserved for analysis. It was at half-past one o'clock that Parr first showed symptoms of poisoning.

Shortly after five o'clock his pulse dropped to 80. Then followed the depression consequent upon the suffering he had undergone, and, as he sank, his pulse increased to 150.

At ten o'clock the battery was applied to the sinking man. His pulse was lowered by the application, and varied from 102 to 108. The battery was applied along the spinal column up to the back of the neck, to his breast, stomach, and each side of the neck. When it had been applied for some time, it produced frothing at the mouth, and apparently woke him up to a certain degree from the stupor he was in. At the expiration of twenty-five minutes the battery was removed, and his pulse fell to 100, and his respirations became more natural, falling from 26 to 24; the number in health averaging 18 per minute.

At half-past eleven o'clock, Parr's pulse beat 108, and the respirations numbered 27 per minute. At twenty minutes past twelve o'clock the battery was again applied, but with less effect, and at half-past one o'clock it was again tried with the same result. At three o'clock the pulse was 108, and the respiration 26. At that hour the physicians succeeded in introducing milk into the stomach, and from the indications then his prospects of recovery were considered good.

At ten minutes after three o'clock Parr rallied wonderfully, and made a desperate effort to rise. He was perspiring freely; large drops of perspiration were running down his face. He deliberately put his hand to his head and wiped the drops away. He raised himself up, and said: "Oh, my! Oh, my!" and then fell back. The attending physicians then raised him up and held milk to his lips, when he drank nearly a cupful. A small quantity of it gargled up in his throat, and, upon being told to spit it out, he did so. Shortly afterward he was given another cupful of milk, which he also drank.

His head was then laid back again, and he turned over on his left side. At this point the physicians were hopeful, and there was every indication of returning consciousness and recovery. After a time he was again turned over on his right side, and his pulse came up with more volume. Half an hour afterward he was given six ounces of beef-tea. He continued in about the same condition until half-past four o'clock, when his pulse ranged from 102 to 108, and his respiration from 26 to 28. After that time he again fell into a stupor, and gradually began to sink. He was then given a raw egg beaten up in milk. About a quarter of five he commenced to gasp, his respiration going up to 42 and his pulse to 120. He continued sinking until ten minutes of six, when he gave a long gasp, after which there was an interval of half a minute, then another gasp, with an interval of a minute, and, finally, a long deep gasp, which was his last. His death occurred at exactly eight minutes of six o'clock. He died very quietly. During his treatment hot bricks were constantly kept at his feet to keep up the temperature.

It will thus be seen that nearly *seventeen hours* elapsed between the ingestion of the poison and death.

We have italicized several sentences in our description of the treatment of the case, in order to call attention to the remarkable remedies employed as antidotes for strychnia. The treatment attempted by the

attending physicians was, indeed, so unique as to call forth a card from a well-known therapist and practitioner, of Philadelphia, which appeared in the *Public Ledger* of June 12th, in which he begged that it should not go upon record as the "Philadelphia treatment of poisoning by strychnia," and went on to show that tannic acid and preparations containing it, such as infusions of coffee, white-oak bark, etc., rendered strychnia inert, and that its physiological antidote is chloral hydrate, administered between the paroxysms; that the convulsions should be controlled by chloroform inhalations, and that the patient should be kept perfectly quiet, as any shock to the surface would bring on a paroxysm. The writer further proceeded to remark that it was, of course, evident that the electric battery, which is so useful in opium poisoning, was entirely out of place in Parr's case—the danger being in keeping the patient awake, and not in allowing him to go to sleep.

It is really amazing to us that intelligent physicians should display such gross ignorance of the laws of therapeutics as was done in this instance, thus laying themselves dangerously open to the charge of malpractice.

At the post-mortem examination, it was found, upon removing the scalp, that there was a depression on the left side of the skull, which was thoroughly healed, but which was plainly visible on the inner wall of the skull, forming an osseous protuberance. It was agreed, however, by all the physicians present that this fracture had not affected the dura mater, and that its existence would not necessarily make the deceased irresponsible for his actions. The brain was removed and carefully examined, and was found to be in a normal and healthy condition, with the exception of a slight congestion, which was probably caused by the convulsions following the ingestion of the poison.

The analytical chemist to whom the contents of the prisoner's stomach had been submitted for examination, reported that it contained small quantities of strychnia.

This case has seemed to us to present two points of much interest, viz., 1st, the novelty of the line of defence adopted by the counsel appointed for the prisoner by the court; and, 2d, the utterly irrational and unprofessional manner in which the poisoned man was treated by physicians of experience and intelligence, several of whom occupied positions of great responsibility in hospitals and dispensaries, and from whom the public would be led to expect an accurate knowledge of the plan of treatment proper to be pursued in such an emergency. M.

THE METRIC SYSTEM AND ITS PRACTICAL APPLICATION.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—Having always been opposed to the adoption of the metric system in writing prescriptions (for the reason that mistakes were sure to occur through druggists being unaccustomed to use it), the writer now wishes to record his first experience in that line.

Not long since I wrote a prescription for morph. sul., 0.06 (nearly equal to gr. j.), to be made into four powders, one to be sprinkled on blistered surface every four hours if required. The druggist (one of the most pretentious on Broadway) put up gr. x., each powder containing gr. iiss. Luckily I saw the medicine before any was used, and discovered the mistake.

Your correspondent has written his last prescription in the metric system, until after the druggists of this city have been before the Examining Board on this point.

M. S. BUTTLES, M.D.

20 E. 25TH STREET, JUNE 5, 1879.

SUCCESSFUL VACCINATION.

DOES IT PROVE THAT SMALL-POX HAS NOT BEEN RECENTLY EXPERIENCED?

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—In your issue of the 14th June, Dr. C. Irving Fisher asks: "Does successful vaccination prove that small-pox has not been recently experienced?" The notes below are gathered to lead him to a more particular investigation of the subject, should he desire it.

A large number of experimenters, who have claimed to produce vaccinia on individuals once attacked with small-pox, have failed in their inoculations on all these subjects; such are Pearson (*Brodley's Phys. and Med. Journal, übersetzt von Kühn, 1801, p. 506*); Hessert (*Hessert und Pilgers Archiv für Kuhpock. Impfung, chap. i., p. 38*); Faust, Sybel, Lavater, Gray, Hellweg, Buchholz, are cited by the latter in his writings on vaccine; Ballhorn and Strohmeier (*Journal de Hyg., vol. x., cah. 3, p. 127*); Otto (*Altenburger Annal., 1801*); Neuhof (*ibid., 1801*); Sæmmering et Lehr. (*Prüfung der Schutzblättern, etc., Frankfurt, 1801*); Goltz (*Hessert und Pilgers Archiv, etc., cah. 2*); Gessner (*Hartenkiels med. chir. Zeitung, 1802, vol. iii., p. 252*); Michaëlis (l. c.); Hardege le jeune (*Journ. de Hyg., vol. xxiii., cah. 2, p. 115*); Sacco (o. e.), etc., who have all concluded from their experience that a perfect vaccination is as rare among those who have had small-pox as a second case of small-pox.—"Traité sur la vaccine, ou recherches historiques et critiques, etc.," p. 780.

Jenner at first cited a certain number of successful vaccinations following variola. Nevertheless, he requested other experimenters to verify his opinion, who admitted the possibility of a good vaccination after perfect variolation. (Ballhorn, Bremen, 1799, pp. 13, 15, 17; and Jenner's Further Observations, p. 42.)

Woodville saw a case in a man who took cow-pox from the animal by contact, but who, when an infant, had had variola. He also produced a good vaccination in a woman who, in her youth, had had variola; but he had never produced vaccine in individuals who had had variola a short time before. His conclusion was, therefore, that for a vaccination to be successful there must exist an interval of many years between the appearance of the variolous eruption and vaccine inoculation (Steinbrenner, pp. 780, 781).

On an examination of Steinbrenner (pages cited *et supra*) many cases will be found bearing upon the points in question, and to this most exhaustive work Dr. Fisher is recommended.

Woodville, in his "Examination of the Report of the Committee of the House of Commons," etc. (London, 1802), quotes a celebrated and experienced surgeon, Mr. Thomas Nash, as follows: "I have not been able yet to determine whether a person who has had the small-pox can receive [cow-pox]."

I have many times attempted vaccination in persons who have previously had small-pox and varioloid, after short and long intervals between their attack of

small-pox. To prove the point, though, would require an immense number of experiments, and for this we must look to the literature of the subject when vaccination was more highly esteemed and assiduously cultivated than now, viz., from the time "Jenner's Enquiry" was published to the appearance of the great works of Bousquet and Steinbrenner. Those vaccinators who have had large experience, particularly since the introduction of Beaugency virus by Dr. H. A. Marin, may have some unpublished records; but, as the matter now stands, it is safe to reiterate "that a perfect vaccination is as rare among those who have had small-pox as a second case of small-pox."

Yours very truly,

THOMAS F. WOOD.

WILMINGTON, N. C., JUNE 18, 1879.

New Instruments.

DRESCHER'S POCKET ELECTRO-MAGNETIC MACHINE.

THIS new and portable machine resembles in style and appearance the French "GaiFFE" instrument, but embodies such important improvements as permits it to produce, with the same charge, an electric current of greater intensity and longer duration than in any instrument now in use. This apparatus can also be obtained at much less cost than the French battery. It is made of three sizes: with one battery cell, with two battery cells, and what is known as the superior two-celled machine, Fig. 3. It is manufactured by F. G. Otto & Sons, 64 Chatham St., New York.

FIG. 1.

FIG. 2.

FIG. 3.

The improved pocket machines are all fitted with Drescher's patent annular cells. These are constructed simply of an annular carbon cup (see Fig. 1), which in itself constitutes the negative rheomotive element of the cell, and for its positive element has an annular

zinc plate (see Fig. 2) supported by and revolving upon an insulated central pillar. The concentric construction of the cell exposes in the smallest space the largest possible surface of both zinc and carbon to the action of the contained oxidating fluid. One of the small Dresser cells is therefore more powerful, and will generate a current of far greater intensity than an ordinary cell of two or three times its size.

To charge the galvanic cell, remove the annular zinc plate from the carbon cell; fill the latter half full of water, and add two spoonfuls (a suitable spoon for the purpose accompanies each machine) of bisulphate of mercury. Replace the zinc, revolve it to dissolve the mercury, and the cell is ready for use.

To start the machine, elevate the angular lever P, turning it toward the magnet. The vibration of its armature, producing a buzzing sound, will indicate that the machine is in action. The rapidity of the vibrations is regulated by elevating the lever more or less. Single shocks in slow or rapid succession may be given at will, instead of the ordinary intermittent current produced by the vibrations of the armature, by pressing the lever P down upon the small button beneath it. A shock will be imparted at each break of the contact.

After use the cells should be removed, washed, dried, and replaced before the machine is set aside.

To obtain the primary (mild) current in No. 3 machine, insert the ends of the two electrode cords into the holes PP and N, and connect the other ends with the handles of the electrodes.

To obtain the secondary (strong) current in No. 3 machine, insert the two ends of the electrode cords respectively into the holes marked P and NN.

To obtain the combined primary and secondary currents in No. 3 machine (producing a current of maximum intensity), insert the ends of the electrode cords respectively into the holes marked PP and NN.

To obtain the primary (mild) current in No. 1 and 2 machine, insert the two electrode cords into the holes 1 and 2.

To obtain the secondary (strong) current in No. 1 and 2 machine, insert the two electrode cords into the holes 2 and 3.

To obtain the combined primary and secondary currents (producing a current of maximum intensity), insert the ends of the cords into 1 and 3.

The strength of all the currents is regulated by means of the metallic tube F. By pulling this tube outwards the strength of the current is increased. By pushing it inwards the strength of the current is diminished.

A NEW VAGINAL AND RECTAL SYRINGE.

By W. THORNTON PARKER, M.D.,

LENOX, MASS.

THERE are a great number of vaginal syringes already in use, but among them all we have not found a good one, unless we except Higginson's, of England. Some throw too violent a stream of water, and are of course injurious. Some throw the stream into the uterus, instead of against the walls of the vagina. Some are too small, some are rough, and none are sufficiently flexible.

To meet a want in our own practice, and to remedy defects which detract from the utility of the instruments now commonly in use, we have devised a syringe, manufactured by Messrs. Tiemann & Co., of New York City. This syringe is made entirely of

rubber, and the vaginal and rectal tubes are perfectly flexible. There is no terminal orifice, but the sides are perforated with "velvet eyes" for a distance of nearly two inches from the end. These rubber syringe-points do not lacerate the mucous membrane, nor produce the injury so often caused by the hard metallic

tubes. The bulb and tubes are large, and insure a copious supply of water. It has already been examined by several physicians, and all have expressed their satisfaction with its working, and their belief that it will be an invaluable aid in the treatment of vaginal and rectal affections.

Obituary.

WILLIAM TILBURY FOX, M.D.

Dr. WILLIAM TILBURY FOX died suddenly in the city of Paris, June 7, 1879, at the age of forty-three years. For the last six years he had been aware that he suffered from serious aortic disease, which was likely at any time to have a sudden and fatal termination. The death of his friend Dr. Murchison greatly shocked him. Wearing with work, he began to feel the necessity for some rest to enable him to complete the summer's work, and went to Paris for a week's relaxation. He had had several attacks of angina. He and his wife dined with an old friend on Friday evening, and he retired in his usual health, intending to return to London on the following day. At two o'clock he was attacked again with angina, from which he succumbed at an early hour Saturday morning.

Dr. Fox was the son of a physician, and was born in 1836 in the south of England. He entered the medical school of University College in 1853, where he displayed a special proficiency in pathology. He was the recipient of honors in anatomy, physiology, and surgery, in the University of London, and obtained the degree of Doctor in Medicine in 1858. At the University College Hospital he was house-surgeon to R. Quain, and house-physician to Jenner, and it was from the last-named teacher that he acquired his early knowledge of skin diseases. His first appointment was that of resident surgeon to the Lying-in Hospital at Lambeth. In 1859 he began general practice, but soon determining to practice as a physician, he selected the specialty of midwifery, wrote papers on phlegmasia dolens and puerperal fever, and was appointed physician-accoucheur to the Farringdon General Dispensary. He soon elected, however, to resume his favorite study of skin diseases, and wrote on "Parasitic Skin Diseases" in 1863, and on skin diseases generally in 1864. In 1864 he made an extensive tour through the East, and suffered severely

from what was thought to be rheumatic fever and dysentery. If his heart, at that time, was affected he was not aware of it, although he returned much enfeebled. In 1867 he wrote pamphlets on the spread of cholera in the East, and the dermatology of Egypt, and began the practice of skin diseases in London. He held the position of physician at Farringdon-Street, and was lecturer on skin diseases at the Charing-Cross Hospital. He was afterwards physician to the Skin Department at University College Hospital, which office he held at the time of his death. In 1869-70 he delivered the Lettsomian Lectures on Eczema, and re-edited, with additions, Willan's Atlas of Skin Diseases in 1875. He was the author of numerous papers on skin diseases, and, with Dr. Farquhar, drew up a report on the "Endemic Skin Diseases of the East." His confrères state of him that he will be remembered as an excellent and successful teacher. He was intensely energetic, loved his work, and was ambitious to place dermatology on a sound scientific basis. As a physician, he was loved by his patients, both in private and in hospital practice. In his death the profession has met with a loss that cannot be readily supplied. As a man he was honorable, upright, and conscientious in the discharge of all his duties, and lived an exemplary Christian life. For many years Dr. Fox was editorially connected with the London *Lancet*, and was at work till the last. He died in the midst of his labor and of his usefulness, and it was his special request that his brother, Dr. Thomas Fox, should pursue the same course of study, and finish his uncompleted work.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from June 22 to June 28, 1879.

O'REILLY, R. M., Capt. and Asst. Surgeon. His leave of absence, granted him May 28, 1879, from Headquarters, Dept. of the South, extended one month. S. O. 24, Div. of the Atlantic, June 25, 1879.

FITZGERALD, J. A., Capt. and Asst. Surgeon. The sick leave granted him in S. O. 42, Feb. 20, 1879, from A. G. O., extended twelve months on surgeon's certificate of disability. S. O. 147, A. G. O., June 23, 1879.

ADAIR, G. W., 1st Lieut. and Asst. Surgeon. Granted leave of absence for two months and fifteen days. S. O. 145, A. G. O., June 20, 1879.

TURRILL, H. S., 1st Lieut. and Asst. Surgeon. Granted leave of absence for two months. S. O. 148, A. G. O., June 24, 1879.

POWELL, J. L., 1st Lieut. and Asst. Surgeon. The order relieving him from duty at Fort Griffin, Texas, and directing him to report at Dept. Headquarters for further orders, is suspended until further orders. S. O. 130, Dept. of Texas, June 21, 1879.

DAVIS, WM. B., 1st Lieut. and Asst. Surgeon. Temporarily detached from Fort Totten, to repair to Fort Buford and to hold himself in readiness to proceed to Fort Peck for duty at the Supply Depot to be established at that place. S. O. 64, Dept. of Dakota, June 15, 1879.

INEBRIETY CAUSED BY STROKE.—Dr. T. D. Crothers, superintendent of Walnut Hill Asylum, Hartford, Conn., reports (*Med. and Surg. Reporter*, January 25th) five cases of inebriety caused by a previous stroke. He concludes that this form of inebriety "is more or less incurable."

Medical Items and News.

CONTAGIOUS DISEASES.—WEEKLY STATEMENT.—Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending June 28, 1879.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
June 21, 1879.	0	11	114	2	65	24	12	0
June 28, 1879.	0	4	103	2	40	28	1	0

THE SANITARY CONDITION OF YELLOW FEVER DISTRICTS.—We are happy to be able to chronicle that official reports from the Mayors and Presidents of Boards of Health of Memphis and Collierville, Tenn.; Vicksburg, Jackson, Canton, Grenada, and Holly Springs, Miss.; Shreveport, La.; Hickman, Ky.; Helena, Ark.; Decatur and Tusculumbia, Ala., bring the intelligence that in none of the places mentioned has the health outlook ever been more favorable. In no instance has there been any indication of a return of the fever. Better health than is usual at this season of the year prevails, and every preventive that sanitary knowledge can suggest has been made use of to preclude a recurrence of last year's epidemic. Quarantine regulations have been established, and are ready to be enforced should exigency arise.

PHOSPHORIC EMULSION IN PHTHISIS.—R. Pure cod-liver oil, f ʒ iv.; Glyconine (made by thoroughly triturating equal parts of glycerine and yolk of egg) f ʒ ix.; Jamaica rum, f ʒ ij.; Dilute phosphoric acid, f ʒ ss. to f ʒ ij.; Essent. oil bitter almonds, gtt. xx. Add the latter to the glyconine, then add the cod-liver oil *drop by drop*, stirring vigorously all the time; then add the rum and acid. Dose: average for an adult, one tablespoonful after each meal, being mainly regulated by the amount of phosphoric acid to be given.—(MARTIN L. JAMES, M.D., in *Trans. Med. Society Va.*; formula taken from *Archiv. Elect. and Neurol.*, May, 1874.)

THE LONG ISLAND COLLEGE HOSPITAL.—The twentieth annual commencement exercises of the Long Island College Hospital were held June 25th, and the degree of Doctor in Medicine was conferred on thirty-three graduates, twenty per cent. of the applicants being rejected. The Academy of Music was filled to overflowing. The degrees were conferred by Theo. L. Mason, M.D., President of the Collegiate Department. The address was delivered by Rev. William A. Snively, S.T.D. The valedictory was delivered by E. H. Bartley, M.D., of the graduating class. Music was furnished by Grafulla's Band.

VADE MECUM OF EQUINE ANATOMY, by A. LIAUTAUD, M.D., V.S., Prof. of Comparative Anatomy to the American Veterinary College, etc., etc. New York: Published at the American Veterinary College, 141 West Fifty-fourth Street, 1879.

Original Lectures.

THERAPEUTICS OF DIARRHOEA IN CHILDREN.

By A. A. SMITH, M.D.,

NEW YORK.

LECTURER ON MATERIA MEDICA, THERAPEUTICS, AND CLINICAL MEDICINE, IN BELLEVUE HOSPITAL MEDICAL COLLEGE.

GENTLEMEN: I desire to call your attention to day to diarrhoeal troubles, especially those apt to affect children, not alone infants, but those under seven or eight years of age. It would be impossible to go over much of the subject in an hour; I shall therefore make my lecture suggestive, and touch only some of the most important points. Whatever the cause, all children, whether infants or those older, ought to be kept quiet when suffering from diarrhoea. They should be kept in a partially darkened, quiet room, free from noise, and all talk in the room should be avoided, especially when the child is asleep. The nervous system in childhood is so impressible it is easily disturbed, and any disturbance of this character aggravates the diarrhoea. Infants under one year ought to be kept lying down as much as possible. They should not be jolted up and down as is the custom of most nurses and some mothers, in order to amuse them. If the child is under one year, let it be placed on a pillow, if the diarrhoea is severe, as it can be kept quiet more easily in this way than when lying on the lap. Even in changing the napkin care should be taken to move the child as little as possible. Don't be afraid to keep the room well ventilated in which the child lies. Mothers usually are over-careful for fear the child may take cold, and on this account are apt to keep the room too closely shut up. When the child is awake it can be carried carefully into open air, always in the shade. Salt-air is beneficial to almost all forms of diarrhoea in children, and this is especially so in regard to city children. We in the city, therefore, urge a ride on the salt water, or taking the child to the sea-shore if possible. In all cases, in children under a year, if the diarrhoea is severe, keep warm applications over the abdomen; make a spice bag. Take a half ounce each of cloves, allspice, cinnamon, and anise seeds pounded, but not powdered, in a mortar, put these between two layers of coarse flannel, about six inches square, and quilt them in. Soak this for a few minutes in hot spirits (brandy, or whiskey, or alcohol), and water equal parts, and apply it to the abdomen warm, renewing it when it gets cool. In this way we not only get the effects of a poultice, but we also get the sedative and antiseptic effects of the spices. Great heat, with influences that depress the nervous system, bad hygienic surroundings, improper diet, too early weaning, bottle food, and dentition, are among the causes that predispose to diarrhoea. In all cases remove the cause if possible.

METHOD OF REDUCING TEMPERATURE.

There is one symptom common to almost all cases of diarrhoea if severe, and in my opinion it is the most important, and that is the increase of temperature. The best means of reducing the temperature is by the external applications of cold. Since we have the Kibbe's cot, which you have seen here, the immersion of the child in a bath is practically done away with. The Kibbe's cot can be improvised easily; it is a pleasant and convenient way of giving the wet pack; is just as effectual as the bath, and has very few of its

objections. Fold a small sheet so that it will cover the child from the axillae to the ankles, place the child on the bed, leaving the arms and feet uncovered. The axilla can be dried easily, and the temperature be taken while the child is in the pack, or the thermometer may be introduced into the rectum, the most accurate way of taking the temperature. Water of the desired temperature may be poured on from a pitcher. In cases of slight elevation of temperature, say to 102° F., or under, sponging off the body with water about the temperature of 80° F. will usually answer the purpose, and it may be done often enough to reduce the temperature nearly to normal. But in all cases of an elevation of temperature above 102° F. resort to the Kibbe's cot or its substitute. Always remain and make the first application yourself. The parents will be timid about it. The child will cry, and it will be necessary for you to show them by the good effects produced, the wonderful power by this means of reducing temperature, of calming the restlessness and irritability of the child, and of inducing sleep. Afterward you can teach them the use of the thermometer and the methods of application of the water. The temperature of the water may be at first 90° F., then gradually, as the child becomes accustomed to it, it may be made cooler until it is brought down to 80° F. in a few minutes. It may be necessary where the temperature is very high, or where it rapidly rises after it has been reduced, to apply the water even colder than 80°. Reduce the temperature to 99°. It usually goes down still farther after the child is taken out. Remove the sheet, put the child in a thin blanket, cover it up and let it sleep. It may be left in the pack twenty or thirty minutes, longer or shorter according as you find the temperature down to 99°. In very severe cases, where the temperature rises to 105° F., or higher, it may be necessary to apply the cold every hour or two. In such cases you need not remove the child from the Kibbe's cot, but let it remain there for several days if necessary. The cot may be made comfortable by folding a woollen blanket and putting it under the child. I cannot speak too emphatically of the importance of the reduction of temperature in the treatment of the diarrhoeas of children, and of this means of accomplishing it. It is, however, only an aid to other means of treatment.

NURSING AS A CAUSE OF DIARRHOEA.

One of the most frequent causes of diarrhoea in young infants is too frequent nursing. The child, when a few days old, can be taught to nurse about every two hours during the day, and every three hours at night. My first question, when I am called to see an infant under six months suffering from diarrhoea, is, "How often does the child nurse?" and frequently find it has no regularity of nursing, sometimes nursing as often as every half-hour. By establishing regularity of nursing, the diarrhoea is often cured. A child under four months, as the rule, will have two, sometimes three evacuations in twenty-four hours. This number is within the range of health. You will see many cases of diarrhoea with very little constitutional disturbance, but frequency of movements and the appearance of the movements not particularly unhealthy. Bismuth, subnitrat., three grains every two or three hours, will cure such cases.

PRETERNATURAL ACIDITY.

Some infants have a tendency to preternatural acidity in the digestive organs. The diarrhoea that occurs in such cases is accompanied with considerable pain, the passage of small, cheesy looking masses

with the stools, the odor sour, and sometimes even offensive, the reaction decidedly acid. Such children may be given, with good effect, a teaspoonful of lime-water three times a day. Give it in two teaspoonfuls of milk. Chalk may be given. The mist. cretae of the Pharmacopœia is a good preparation to give. It contains, besides the chalk, gum arabic, glycerine, and cinnamon, all of them good in this form of diarrhœa. Sometimes it is well to give a laxative, as some of these cheesy masses may have collected in the intestines and may be acting as an irritant. The indication is to remove them. I have found the following prescription a better one to give than the traditional castor-oil:

R. Pulv. rhei rad. gr. xv.
Sodæ bicarb. gr. xxv.
Aq. menth. pip. ʒ ij.
M. Sig. ʒ j. as laxative to a child from one to four months old.

In this prescription we get the laxative effects of rhubarb with its so-called secondary astringent effects, the alkali, and the sedative, and antiseptic effects of the peppermint.

In any case of diarrhœa, where there is reason to believe there is any irritant in the intestines, the treatment may be commenced by giving a laxative to remove it.

DENTITION AS A CAUSE OF DIARRHŒA.

Between the sixth and twenty-eighth month dentition plays a very important part in the production of diarrhœa. It might be called a nervous diarrhœa, for it is probably due to reflex nervous disturbances. If dentition is not directly responsible for many of these diarrhœas, it is indirectly so by putting the system in a condition to be more susceptible to all those influences which do produce diarrhœa. In all cases where the gums are swollen, lance them. In any case where it is about time for the tooth to come through lance the gums over the tooth thoroughly and draw some blood. I believe the disturbance is often due to pressure of the tooth deeply in, and before it shows much swelling on the surface. Lancing the gums never does harm. It is better to err on the side of lancing them when there may be no necessity, than to fail to lance when there might be necessity. I have often seen a child having from ten to twelve movements a day relieved entirely by lancing the gums, and with no other treatment. It is in these cases that the bromides prove so effectual. Give the following combination of a bromide with mucilage to a child between six months and a year; older children a larger dose:

R. Sodii bromid. ʒ ss.
Mucilag. acaciæ,
Aquæ puræ, ʒã q. s. ad. ʒ ij.
M. Sig. ʒ j. q. ʒ h.

The bromide diminishes the reflex disturbance, and the mucilage is soothing to the irritated intestinal mucous membrane.

ERRORS IN DIET AS A CAUSE OF DIARRHŒA.

Another cause of diarrhœal troubles is the giving of all sorts of diet too early. There is a desire to make the child strong and grow more rapidly. Meat, vegetables, and farinaceous articles in abundance are given to children even eight or ten months old. A child under eight months ought to have no other diet than milk, and even up to two years milk should be its main diet. Human milk is the best during the

first year, or until weaning; but often from necessity the child is brought up on the bottle. During the first eight months cow's milk diluted one-fourth with barley-water makes the best diet. The ground or crushed barley should be boiled with water of sufficient quantity, so that when cold it is about as thick as thin cream. The milk should be given about blood-warm and a little sweetened. What place should condensed milk be given in the feeding of children? I should give it a place on the shelf at the grocers. I have tried the condensed milk with children thoroughly, and have seen it tried in the practice of others, and must protest against its use. Children fed on condensed milk, although they may thrive well apparently, yet when they fall ill show very little resisting power, and, particularly when they fall ill of diarrhœa, they weaken very rapidly and the diarrhœa is apt to be obstinate. There are exceptional cases in which it may be used, and some cases in which it is desirable to use it for a short time. When bottled children suffer from diarrhœa it is well to boil the milk and make the barley-water thinner and give more of it, say one-third barley-water to two-thirds boiled milk. I have found thoroughly cooked wheat-flour an admirable food for children with diarrhœa. Have it prepared in this way: Put about two pounds of flour in a muslin bag, tie a string around the top of it, and suspend it in a kettle of water and boil it for five hours; then let it get cold. Take off the bag, cut off the outside dough and grate it. Thicken boiled milk with this to about the consistency of a thin gruel, or about thick enough for it to pass through the rubber nipple of a nursing-bottle. All food for children should be thoroughly cooked. Still more is this to be observed when they are ill of diarrhœa. As a rule, feed children suffering with acute diarrhœa just as little food as will satisfy their hunger, and often a little cold water will relieve their thirst and lessen the desire for food. Avoid alcoholic stimulants, unless there is exhaustion. Champagne iced may be given in small quantities, if there is obstinate vomiting.

FLATULENT DIARRHŒA.

There is a flatulent diarrhœa which occurs in young children and gives much trouble. The movements are frequent but very small, and the flatulence is sufficient to keep the child awake nights.

I have found the following prescription an excellent one in such cases:

R. Magnes. calcin. ʒ i.
Spts. amm. aromat. ℥ xl.
Tinct. assafœet ʒ i.
Anisette ʒ vi.
Aq. cinnamomi q. s. ad. ʒ iv.

M. Sig. ʒ i. every half-hour until relieved, to a child from three weeks to four months old. Two or three doses will usually relieve.

DIARRHŒA DEPENDENT ON NON-DIGESTION OF SUGAR.

There is a diarrhœa which occurs in the summer, characterized by frequency of discharges; the movements are green, accompanied with pain, and in many cases the stomach is so irritable that vomiting is a troublesome symptom. Probably the diarrhœa is due to non-digestion of sugar. In connection with such cases I would like to call your attention to kumyss or fermented milk. In this preparation the milk has already taken the first step in digestion. There is or ought to be no sugar in it: the casein is in a fixed condition, and consequently cannot undergo the changes of coagulation and putrefaction, and there is a small quantity of alcohol, but it is in such a com-

bination that it is easily assimilated. The kumyss is charged with carbonic acid gas, but children do not take it readily with the gas in. It may be gotten rid of by taking the kumyss out of the bottle and pouring it from one pitcher to another a few times. A small quantity may be kept out for immediate use, and the remainder put back into the bottle, the bottle corked and put in a cool place. Sometimes children who are unable to retain anything else can take a teaspoonful of kumyss at a time and digest it, and frequently without any medicinal treatment will recover under its use. Twelve hours is as long as it can be kept safely, after once uncorking it. The child need take no other food while it is taking the kumyss. It is itself food and drink. It is sour, and mothers are tempted to sweeten it to make it palatable. Of course it should never be sweetened, and should never be given within two hours after any other form of milk, and should be given cold. After the first repugnance to it children take it quite readily; even children as young as six or eight months can be made to take it by taking advantage of their thirst and giving it at first in small quantities. Kumyss may be used in many forms of diarrhœa because of its easy digestion. That made by Dr. E. F. Brush, of this city, is the only preparation of it I have found reliable.

DYSENTERIC DIARRHŒA.

There is another form of diarrhœa quite common in summer, characterized by what are known as dysenteric discharges, that is, quite frequent evacuations and straining, as in dysentery, and the evacuations are about the consistence of pudding, or thin jelly, and are usually of a pinkish color. This pinkish color is due to the admixture of blood and mucus with the substance that passes the bowels. I have found small doses of castor oil and opium, given in mucilage, an excellent combination in such cases, as in the following prescription:

R. Ol ricini. ℥ i.
 Sacch. lactis. ℥ ss.
 Tinct. opii camph. ℥ xxxij. to ℥ iss.
 Mucilag. acacie.
 Aque pure, añ q. s. ad. ℥ i.
 M. Sig. ℥ i. q. 2 or 3 hours.

Add the pargoric according to the age of the child. For a child under a year, four to eight drops. For child of one to two years, ten drops. Don't forget the general suggestions in regard to diet in all cases of diarrhœa. It is well sometimes in these cases to give starch-water enemata. If the enemata are given the pargoric may be left out of the castor oil mixture, and laudanum may be put in the enema. One or two drops of laudanum with one to three tablespoonfuls of starch-water, may be given according to the age of the child. The starch-water should be made about as thick as thin cream, and given tepid. It may be repeated every three to six hours, according to the severity of the attack.

INFLAMMATORY DISORDERS.

There is a large class of summer diarrhœas included under the term of inflammatory disorders. They are accompanied with great pain; frequency of movements; there may or may not be a small quantity of blood passed with the movements, more or less increase of temperature, with disturbances of the nervous system, and there may or may not be gastric irritability. The indications are to reduce the temperature, manage the diet according to the directions I have given you, surround the child by the best possi-

ble hygiene, put the warm applications over the abdomen, and give internally a combination of opium and camphor. Tully's powder, which consists of morphine, camphor, and prepared chalk, makes a good combination. The dose for an adult is the same as Dover's powder. Ten grains contain one-sixth of a grain of morphine and a little over three grains of camphor. A child three to six months old may be given an eighth of a grain every two to six hours, according to the severity of the attack and the control the powder has over it. A child six to eighteen months may be given one-sixth to one-fourth of a grain in the same way. After the acute symptoms have been controlled there remains in many cases a tendency to looseness of the bowels, with very little constitutional disturbance. Stop the Tully's and give the following:

R. Ac. sulph. dil. ℥ xxiv.
 Salicin. gr. xxiv.
 Glycerine. ℥ iij.
 M. Sig. ℥ i., t. i. d.

Do not give it within a half-hour of the taking of milk. The sulphuric acid has a tonic and astringent effect, and the salicin, besides its tonic effect, acts also as an anti-fermentative.

CHOLERA INFANTUM.

And now, as to the treatment of a disorder of children, which is the dread of all physicians, especially young ones, and justly so, for it is a formidable disease. I look upon cholera infantum as a disorder of the nervous system, and the disturbances of the alimentary canal as only the local manifestations of a constitutional disorder. It occurs from great heat, but it has always seemed to me that in addition to great heat there was some other element. I have noticed that cases are much more frequent when, besides great heat, there were certain atmospheric influences which depress the nervous system greatly. "Dog days," as they are called, are very fruitful in the production of cholera infantum. Among the poor, great heat, poorly ventilated rooms, poor hygiene in all its forms and with all its attendants, improper food, particularly bottle food, favor the development of the disease. I recognize two varieties of cholera infantum, and divide them, according to their manifestations, into congestive and exhaustive. In the congestive form there is redness of the surface of the body, especially about the face and head; redness of the conjunctivæ, great elevation of temperature, the pulse rapid and full, the nervous symptoms marked, twitching of the muscles, and frequently convulsions; the vomiting and purging violent, the matters vomited and passed being very thin and of enormous quantity. All of these symptoms come on very rapidly, differing in this respect from other forms of diarrhœa. The two special indications are to reduce the temperature and control the nervous manifestations. Apply cold according to the directions I have given you. Give hypodermic injections of quinine and morphine. Give to a child of six months one grain of quinine and about $\frac{1}{16}$ of a grain of morphine every four or six hours, according to the indication. For each additional six months of age an additional half grain of quinine and an additional $\frac{1}{16}$ of a grain of morphine. To simplify the matter I will give the prescriptions of the solutions of quinine and morphine:

R. Morph. sulph. gr. ss.
 Aque destillat. ℥ i.

M. Sig. ℥ v. by hypodermic injection for a child six months old.

R. Quinæ sulph. ʒ i.
 Ac. sulph. dil. q. s.
 Acid carbol. cryst. gr. v.
 Aquæ destillat. ʒ i.

M. Sig. ℥viii. by hypodermic injection for a child six months old.

Usually the stomach is so irritable that medicines and food are both vomited. After the temperature is reduced, and the nervous system is rested, small quantities of food can be given. Small pieces of ice may be given to allay thirst.

In the other variety, the exhaustive form of the disease, there is paleness of the surface of the body; little or no elevation of temperature; indeed, the temperature in some cases is below normal; the pulse is rapid and feeble; the nervous symptoms, although present, are not as marked as in the other variety. The vomiting and purging are violent, the child sometimes getting rid of more fluid in a few hours than it has taken in days. The emaciation is very rapid and great. The indications for treatment are to check this enormous loss of fluid and sustain the patient. Our main reliance must be on opium and alkalies and stimulants, with the general directions I have given you in the beginning of the lecture. Opium in small doses, in addition to the other effects claimed for it, is a cardiac stimulant, thus meeting one of the chief indications in this disease.

The following combination is good:

R. Tinc. opii. camph. ʒ iij.
 Mist. cretæ. ʒ iij.

M. Sig. ʒ i. q. 2 or 3 h. to a child of six months.

Sometimes nothing is retained by the stomach. In such cases, it is necessary for you to give the opium hypodermically. Give the $\frac{2}{100}$ grain morphine as directed in the other variety of the disease, but do not give the quinine.

Alcoholic stimulants should be given. Brandy is the best. Give five drops of brandy in a teaspoonful of water, every hour, to a child of six months, if there is great exhaustion. This quantity may be increased or diminished according to the indications. In some cases of cholera infantum a child becomes suddenly much more exhausted, pulse becomes more rapid, extremities are cold, perspiration comes out freely, and the child seems to be going into collapse. An enema of hot water will sometimes revive such a child wonderfully. Let a good quantity of hot water be used, say half a pint, and hold a towel to the anus afterward, in order to have the water retained as long as possible. Along with this give internally spirits of camphor, from six to ten drops. It may be put in with the brandy, and the two given together for a few hours. In any case of diarrhœa, where these symptoms of great exhaustion occur with the coldness of the extremities, the hot water enemata may be given.

BEEF-TEA.

The very common habit of giving beef-tea in the diarrhœa of children prompts me to say a word in regard to its use. Of course, it is given with a view to sustain the strength of the child, but I have found that almost invariably it acts as an irritant and aggravates the disease. Sometimes it seems to pass the bowels in the same form in which it was taken. In any case of acute diarrhœa I would advise you not to give beef-tea.

OPIMUM.
